A model can be any, necessarily simplified, representation of reality, such as a two-dimensional picture, a three-dimensional model, a sketch, a plan, a schema, a mind map, a flow diagram, a graphical diagram, a computer code, or a set of equations. The idea of mathematical modelling was first fully developed in physics and could be said to have its roots in Galileo’s breathtakingly simple yet ground-breaking combination of observation, algebra, and geometry, applied to a basic human experience—a stone falling under gravity. For Galileo in 1623, philosophy is written in the book of nature, but to understand it we have to master the language in which it is written—mathematics; without mathematics we will be lost and grasp nothing (Galileo 1623/1957). His fundamental insight was to transform the question about the falling stone from the qualitative, philosophical ‘Why?’ to the quantitative, observation-oriented, and empirical ‘How?’ and to see the value of carefully selected measurable parameters under dramatically simplifying assumptions. Galileo started by assuming constant acceleration, on grounds of simplicity. In order to handle the matter in a scientific way, it was necessary to ‘cut loose’ from such irksome difficulties as friction or air resistance. Once we have discovered our theorems about the stone, assuming there is no resistance, ‘we can correct them or apply them with limitations as experience will teach’. ‘It seems we shall not be far wrong if we put the increment of speed as proportional to the increment of time’ (Galileo 1638/1914). Galileo’s basic principles of observation, quantitative questioning, simplifying assumptions, graphical representation, and hypothesis-making and testing lie at the heart of all modern science, and the mathematical modelling that he pioneered is now used in almost every field of intellectual pursuit.

In the context of public health, a mathematical model serves as a conceptual tool for thinking about the behaviour of complex systems and learning how to describe, observe, predict, and control the behaviour of such systems. Such a model is expected to mirror, in useful ways, some of the reality that it represents, and is constructed to imitate selected aspects of this reality. For modelling infections in human populations, models based on algebra and calculus have been widely deployed over a long time. But as the applications become more complex and detailed, analytical solutions become less tractable and computer simulation is increasingly important.

A mathematical model is a set of explicit assumptions about features to be modelled and hence abstracted, together with selected mathematical modes of expression and analysis including variables, functional dependencies, flow diagrams, recurrence relations, differential equations, programming code, and so on. This reductionist approach can give rise to fears that the models are too simplistic and therefore unrealistic. But, as illustrated earlier by Galileo’s primal act of modelling, it is this reductionism that is the key to the success of much science. Far from aspiring to capture reality in all its complexity, the modeller addresses each specific question by careful selection and abstraction of those elements

of reality requisite for the task. A powerful though simple conceptual device in maintaining a clear boundary between real and modelled scenarios, and exploring a 'model world' in its own right, is to think separately about three realms, or objects of our attention: (1) the real world, (2) the abstracted 'model world' per se, where things are simple and fully specified, and (3) the mathematical tool box for manipulating and analysing events in the model world. The point here is to discuss the mathematical and analytical activities by reflecting on their interpretation within the model world.

The value of a mathematical model lies in the extent to which it suggests new insights into the nature and mechanisms of the processes being modelled, or in its ability to make predictions which can be tested and which stand up well to such testing. The model is 'calibrated' by estimating its parameters using known data; the model is 'validated' either by comparing its predictions with appropriately collected data resulting from experiments or trials different from those used in the initial model calibration, or by comparisons with other models' predictions. The fruitful interaction between abstract theory and real-world data is intrinsic to the process of good modelling practice, which we will focus on in the final two sections.

What kinds of questions are we trying to understand?

A primary purpose of modelling is to help us understand the natural history of the infection or disease that we are studying. Fig. 5.18.1 gives the trends in the number of cases of various diseases reported in England and Wales between 1930 and 1985 as presented by Anderson and May (1991).

It is clear from Fig. 5.18.1 that the dynamics of the various diseases are quite different. Diphtheria cases remain high but variable from 1930 to 1940, then decline rapidly, and by 1950 diphtheria is essentially eliminated from England and Wales. The number of measles cases fluctuates with up to fourfold increases, and declines from one year to the next. But what is most striking is the very regular 2-year cycle from 1950 to 1960. Acute polio (paralytic poliomyelitis and polioencephalitis) trickles along steadily until 1941, increases tenfold in 1942, fluctuates for the next 10 years and then declines rapidly to eradication by about 1965. Scarlet fever falls steadily, with some fluctuations, from 1930 to 1985 but is never quite eliminated. Typhoid and paratyphoid seem to come down very rapidly from a high point in 1940, but, since this appears to be an outlier, one might wish

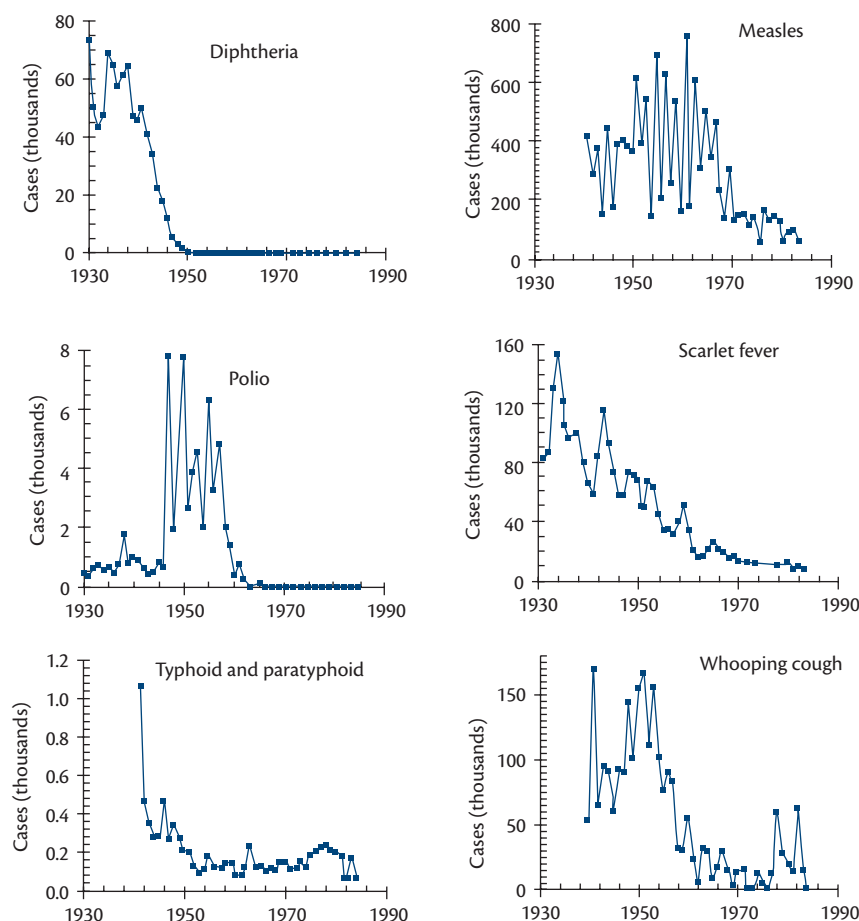

Fig. 5.18.1 Disease trends in England and Wales. The data give the number of cases per thousand people of various diseases from 1930 to 1985.

Adapted from Anderson, R.M. and May, R.M., *Infectious diseases of humans: dynamics and control*, pp. 42–43, Oxford University Press, Oxford, UK, Copyright © Roy M. Anderson and Robert M. May, 1991, by permission of Oxford University Press Inc. Contains data from Topics A–Z, Health Protection Agency, available online at <http://www.hpa.org.uk/Topics/InfectiousDiseases/InfectionsAZ>.

to exclude it. The number then reaches a low but steady level in 1950 with no significant change after that. Whooping cough is particularly interesting. Numbers are very high in the 1950s, fall dramatically in the 1960s and 1970s but then show two 'outbreaks' in 1978 and 1982.

Before we can begin to make models to explain these different trends, we need a better understanding of the individual diseases. Diphtheria is a bacterial infection of the upper respiratory tract, transmitted through contact with saliva, with case fatality rates of 5–10 per cent with higher rates in young children and old people. Vaccination with diphtheria toxin was developed over the course of the twentieth century. The United Kingdom proposed the introduction of mass childhood diphtheria immunization in 1940 (Mortimer 2011) and this led to the elimination of diphtheria by 1950. Only about ten cases are now reported each year in England and Wales.

Measles is a viral disease of the respiratory tract, transmitted by aerosols from infected people. It is highly contagious and almost all those without immunity through previous exposure or vaccination will be infected. There is an asymptomatic incubation period lasting for about ten days after infection and people are infectious for approximately one week. In developed countries about 0.3 per cent of measles cases will die (Orenstein et al. 2004), but in countries with high rates of malnutrition and poor health-care or in people with HIV (Sension et al. 1988) the case-fatality rates can be up to 30 per cent. The measles vaccine, which confers lifetime immunity, was licensed in 1968, after which the number of cases started to decline. There was a further decline after 1988 when the combined MMR (measles, mumps, and rubella) vaccine was introduced.

Polio is a viral disease and may soon be the second disease, after smallpox, to be eradicated worldwide; in 2011 there were only 650 cases in the world. Polio is highly contagious, transmitted mainly via the faecal–oral route when people consume contaminated water or food. In endemic areas, it once infected virtually the entire population. Virus particles are excreted in the faeces for several weeks following infection. Three doses of the live attenuated oral polio vaccine produce protective antibodies to all three poliovirus types in more than 95 per cent of recipients and this was licensed for use in 1962.

Scarlet fever is caused by a toxin produced by a bacterium, most commonly in 4- to 8-year-old children. It is spread mainly by inhalation, and 15–20 per cent of school-age children may be asymptomatic carriers. A vaccine is not available but scarlet fever can be treated with antibiotics.

Typhoid is a bacterial disease, transmitted by the ingestion of food or water contaminated with the faeces of an infected person. Partially protective vaccines are available, but the disease is best prevented through good sanitation and hygiene. Oral rehydration therapy provides a simple way to prevent many of the deaths of diarrhoeal diseases in general and this applies to both typhoid and cholera.

Pertussis, or whooping cough, is a highly contagious bacterial disease and treatment is of little benefit. Vaccination gives protection for 5–10 years, covering childhood—the time of greatest exposure and greatest risk of death. In the 1970s there were suggestions that the vaccine might cause permanent brain damage in very rare cases. Further studies found no connection of any kind between the vaccine and permanent brain injury. However a few

well-publicized anecdotal reports of permanent disability were blamed on the vaccine. Consequently, the immunization rate fell in Great Britain from 80 per cent in 1972 to 30 per cent in 1978. Coverage rates then increased slowly again and reached 90 per cent by 1992.

We can now think about ways in which modelling might help us to understand the patterns of disease shown in Fig. 5.18.1. Diphtheria is fairly straightforward, but we may want to ask why the prevalence in the early twentieth century seemed to be stable at about 60,000 cases per year. We note that, although vaccines were developed prior to 1940, it was only with the introduction of mass vaccination of children that diphtheria was effectively eliminated. We could collect data on coverage over time and see if this helps to explain the rate of decline between 1940 and 1950. We could also model the effect of vaccinating children at different ages.

Measles is particularly interesting. Since the infectious period is very short and infection confers lifelong immunity, measles can only persist because it is highly infectious. This means that it can spread very rapidly, but, since infected people either die or are immune for life, it is also unstable and can burn itself out, leading to the oscillations seen in Fig. 5.18.1. The modelling question is then: why is there this tendency to oscillate with a period of 1 year? The broad answer is that in a small, closed population the introduction of measles will lead to an epidemic that burns out and never recurs. For the epidemic to recur requires new susceptibles and these arise from new births. In England and Wales the birth rate in the 1950s was such that it took about a year to acquire enough susceptibles to sustain another epidemic. So the modelling prediction is that the inter-epidemic period should be shorter where the birth rate is higher and vice versa. We could further take into account that for the first year of life children are protected from measles by maternal antibodies, and that contact rates and spatial heterogeneity also affect the details of the epidemic pattern (Earn 2004). However, we see that after the introduction of vaccination in 1968, measles began to decline, but the *coup de grâce* was only delivered in 1988 with the introduction of the MMR vaccine in that year. The modelling question here would be to compare coverage in the period 1968–1988 and see if this explains the decline.

Polio is still not fully understood even as we approach final eradication of the virus. The tenfold increase after 1940 still demands an explanation. A common explanation is as follows: we know that polio is transmitted through water or food contaminated by the faeces of people with polio and we know that adolescents are much more likely than infants to develop paralytic or acute polio. The suggestion, then, is that improved sanitation and hygiene reduced transmission rates and delayed the age at which people acquired polio, leading to the dramatic increase in 1940. At first glance, this seems unlikely, since improvements in sanitation and hygiene would have happened slowly and 1941 was not a critical year in this regard. An equally sudden upsurge was recorded in the United States, but there the upsurge occurred in 1907, not 1941 (Nathanson and Martin 1979).

Furthermore, there seemed to be no shift in the age distribution of people developing acute polio before and after the sudden change. The explanation for the rise remains open. The very rapid decline after the introduction of the oral polio vaccine in 1962 makes sense. In 2012 there were 222 cases of polio in Pakistan, Afghanistan, and Nigeria combined, five in Chad, and one in

Niger, so that the more interesting modelling question now involves ways to achieve final eradication and to be certain that it has happened (World Health Organization 2013).

Scarlet fever cannot be prevented but it can be treated with antibiotics, and the steady decline, albeit with some residual variability, raises interesting questions for modellers. Early treatment with antibiotics might have reduced the effective infectious period of the disease, but antibiotics only became widely available after the Second World War, and the decline seems to have predated the war. It has been suggested (Londish and Murray 2008) that improved living conditions (particularly with regard to nutrition and housing), implementation of control strategies, and possibly reduced virulence of circulating strains (perhaps the result of a natural evolutionary process favouring diminished pathogenicity to maximize onward transmission) may have had a bigger impact on scarlet fever than the availability of effective treatments.

Typhoid is also transmitted through food or water contaminated by the faeces of infected people, and the decline up to 1950 may well have been the result of improved sanitation and hygiene. One would like to have data on the extent to which sanitation and hygiene improved over this period and perhaps compare it with similar time-series data in other countries.

Pertussis was very common in the United Kingdom, but the introduction of the DPT (diphtheria, pertussis, and tetanus) vaccine in the 1950s, with about 80 per cent of children being vaccinated before their second birthday by 1972, led to dramatic falls in the number of cases. However, with the ultimately unfounded scare that the pertussis vaccine was associated with brain damage in children, coverage rates fell to about 30 per cent and there were substantial outbreaks in 1972, 1984, and 1986. As coverage rates rose again, pertussis came close to elimination (Ramsay 2012). An interesting question for modellers is to explore the relationship between vaccine coverage and cases of pertussis.

When is mathematical modelling appropriate?

It is important to clarify the relationship between modelling and other types of study design. In particular, we will attempt to indicate where dynamical modelling is or is not useful, and what it is uniquely capable of doing. There are some kinds of questions that are more naturally answered by conducting an appropriate epidemiological, clinical, or laboratory study. For example: is malaria prevalence likely to be higher in areas where the prevalence of HIV is higher? Are individuals who share cigarettes at increased risk of chronic bronchitis? Does passive smoking increase one's risk of lung cancer? Does taking aspirin reduce one's risk of heart attack? Do high doses of vitamin C reduce one's risk of cancer? Does washing one's hands regularly reduce one's risk of influenza? Given the incidence time series, what was the food item responsible for a food-borne disease outbreak? In short, in many situations modelling is not the right tool for answering simple factual questions which are at heart biological, or about specific incidents. But there are many important questions, such as questions about the interaction of observations, rules, or assumptions, which cannot be given a satisfactory answer without appealing to dynamical modelling. It is increasingly important in the multidisciplinary world of epidemiology for researchers to sense when they have reached the limits of alternative methods and it is time to call in

the modellers. On the other hand, mathematical modelling can perform a truly useful function in infectious disease study and control only if good epidemiological and statistical methods are applied at all relevant stages of data collection, cleaning, management, and analysis, and in all theory testing.

Identifying which questions are better answered by using dynamical modelling rather than any other method of investigation—systematic reviews, meta-analysis, quasi-experimental design, randomized controlled trials (RCTs), observational studies, ecological analyses, and so forth—is not always easy. To help us think about this we might ask the following: could data feasibly be collected to answer the question directly and without modelling? Is there an underlying process that would produce changing patterns that we might be able to analyse mathematically? Are we trying to move from one scale to another—from individuals to populations, or from populations to individuals? Sometimes the issue is determined by what data are available for attempting an answer. For example, estimating just how protective a vaccine is from clinical trials alone is an epidemiological problem, but estimating protectiveness from population-level data is a modelling problem. Knowing that HIV causes AIDS is a clinical problem, but working out by how much we would need to reduce transmission to eliminate HIV altogether is a modelling problem.

The following points highlight some important general categories of applications of mathematical modelling in the framework of public health to illustrate its power and versatility. Modelling is useful for:

- ♦ Encapsulating the quantifiable essence of a complex situation in a simple framework which can then be used to make estimates. Dual infection or co-infection is a good example; the HIV epidemic has transformed the dynamics of malaria (Abu-Raddad et al. 2006) and of tuberculosis (TB) (Cohen et al. 2006). In particular, we know that people with HIV are at about ten times greater risk of TB, on average, than people who are not infected with HIV. The HIV epidemic has consequently driven up the incidence of TB, in some countries by five or more times (but with a delay of about 5 years between the rise in HIV and the rise in TB). This can in turn be explained by the notion that once an individual is infected with HIV, the risk of developing TB increases with time, only reaching very high values after about 5 years.
- ♦ Translating descriptions of behaviour at one scale (e.g. individual-level epidemiology of a disease) into descriptions at another scale (e.g. population dynamics). For instance, Ross's question about malaria was this: given a certain level of risk (measured as effective biting rate) at the individual level, what outcome might we expect to see at the population level? Using a mathematical model, he found conditions for equilibrium that fitted the data well, and saw how this could be reversed: if one could characterize this equilibrium, then something about individual-level parameters could be inferred, setting useful targets for mosquito control.
- ♦ Enabling extrapolation, with quantified uncertainty, from data measured over a relatively short term to a projection of what is likely to happen in the long-term evolution over time, or from the results of randomized control trials to a particular local setting. The HPTN-052 study (Cohen et al. 2011) showed that ART reduces a person's infectiousness to others by about

96 per cent, but we need models to tell us what the consequences of this would be for controlling the epidemic of HIV in populations.

- ◆ Synthesizing data from different fields into a single framework, thus enabling checks on consistency. In modelling the impact of HIV on TB, we need clinical information concerning the rate of progression of AIDS; we need cellular information concerning the way in which CD4⁺ cell counts decline with time since infection; we need epidemiological data concerning time trends in the epidemic of HIV; we need data on the way in which the incidence of TB varies with CD4⁺ cell counts; we need trial data concerning the extent to which ART reduces the risk of developing TB; and we need economic data if we are to assess the cost-effectiveness of possible interventions against either TB or HIV.
 - ◆ Providing clear guidelines for new data collection strategies when trying to answer specific questions where critical features are missing from the data. This may include identifying what type of data, how much data, and at what temporal and spatial resolution it should be collected, within limited funding constraints.
 - ◆ Identifying the factors that sustain an infection within a population and estimating the relative importance of parameters, thus informing control and prevention programmes. In the case of HIV, factors include sexual behaviour, the use of condoms, the use of contaminated needles among drug users, the extent of intergenerational sex, and the age at sexual debut. Modellers might seek, for example, to compare the effects on HIV transmission of sexual heterogeneity, concurrency, and different mixing patterns.
 - ◆ Making predictions over time of the probable dynamics of prevalence, incidence, and infection-related mortality, under different interventions.
 - ◆ Comparing the impacts and synergies of different combinations of interventions.
 - ◆ Identifying threats to the success of an existing intervention.
 - ◆ Maximizing cost-effectiveness of interventions, hence enabling optimization of use of resources to combat an infection, whether within a hospital, an isolated community, a country, or globally.
 - ◆ Evaluating the economics of different control strategies, and deciding whether programmes should re-allocate funding in response to the new data or scientific breakthroughs (such as the recent finding that ART can substantially reduce the infectiousness of HIV-infected individuals (Cohen et al. 2011)).
- low CD4⁺ cell counts? How shall we spend the available funds (Dodd et al. 2010; Kahn et al. 2011; Delva et al. 2012; Eaton et al. 2012)?
- ◆ Can observed trends in HIV prevalence be attributed to intervention success or failure? More specifically, how much of the observed reductions in HIV prevalence can be attributed to behaviour change programmes or other interventions? Can HIV prevalence be expected to decline in the absence of interventions? In early epidemics, can HIV prevalence rise even in the presence of partially effective prevention programmes? Can we estimate what would have happened in the absence of interventions (a 'counterfactual' scenario) (White et al. 2004; Korenromp et al. 2005; Hallett et al. 2006, 2009; Boily et al. 2008)?
 - ◆ Have HIV prevention programmes had an impact on HIV prevalence in South African youth (Actuarial Society of South Africa 2011)?
 - ◆ In which risk groups is most HIV transmission occurring (Brown and Peerapatanapokin 2004; Johnson et al. 2009)?
 - ◆ Can we translate individual-level efficacy of a hypothetical vaccine in the United States, modelling transmission in heterosexuals, men who have sex with men (MSM), and injecting drug users (IDUs), to population-level impact (Long et al. 2009)?
 - ◆ Can vaccines be beneficial (in terms of reducing mortality) even if they do not reduce susceptibility to HIV (Anderson and Hanson 2009)?
 - ◆ When will the number of AIDS orphans peak in South Africa (Actuarial Society of South Africa 2011)?
 - ◆ Can we project for another few decades the number of person years of ART provision in South Africa (Granich et al. 2009)?
 - ◆ Which would be most cost-effective in increasing life expectancy in an African country with limited ART provision: (1) changing ART initiation CD4⁺ count from current WHO level to 200 or 350, (2) introducing second-line ART, or (3) replacing stavudine with tenofovir in first-line ART (Walensky et al. 2010)?
 - ◆ Which of three different feeding recommendations for HIV-positive mothers should be recommended: (1) exclusive breastfeeding for 6 months, (2) replacement feeding, (3) mixed breastfeeding for 24 months (Piwoz and Ross 2005)?
 - ◆ What is the risk, in a 'real-world' setting where HIV testing is less frequent (as opposed to an RCT setting), that women receiving an ART drug-based microbicide could rapidly develop drug-resistant HIV if they become infected while on the microbicide (Wilson et al. 2008)?
 - ◆ Can male circumcision programmes significantly benefit women (indirectly) by reducing the chance that their partners are infected (Auvert et al. 2005; Nagelkerke et al. 2007; Anderson et al. 2009; Londish and Murray 2008; Hankins et al. 2009; UNAIDS/WHO/SACEMA Expert Group et al. 2009)?
 - ◆ Can vaginal microbicides significantly benefit men (indirectly), because of their partners having a lower HIV risk (Wilson et al. 2008)?
 - ◆ How would the cumulative number of HIV infections averted in non-IDUs compare with the number averted in IDUs, under

Modelling policy choices

In this section we give specific examples of important modelling work in HIV and TB, drawing heavily on the review by Johnson and White (2011). The aim is to showcase the scope and power of modelling in one field at least, to encourage readers to identify where such modelling might be applicable in their own fields of interest, and to indicate where more details may be found.

- ◆ Who should be tested for HIV? Who should be prioritized for ART? Should we offer ART to everyone or only to those with

a programme of provision of syringes and condoms to IDUs (Foss et al. 2006)?

- ◆ Would the impact on HIV incidence of treating sexually transmitted infections be the same if the intervention had been introduced at different stages in the epidemic (White et al. 2008)?
- ◆ What would have happened if the rate at which secondary sexual behaviour patterns (concurrency) are acquired were reduced to zero, at different stages in the HIV epidemic (Johnson and White 2011)?
- ◆ What will be the effect of risk compensation behaviour following the introduction of highly active ART for an MSM group (Bezemer et al. 2008)?
- ◆ What is the effect of pre-exposure prophylaxis on HIV incidence (Abbas et al. 2007)?
- ◆ Is there a significant risk of a self-sustaining epidemic of drug-resistant HIV (Smith et al. 2010)?
- ◆ Could the widespread use of isoniazid preventive therapy for HIV-infected adults lead to the accumulation of drug-resistant TB and have only short-term benefit (Cohen et al. 2006)?
- ◆ Is regular viral load testing the best strategy for initiating, monitoring, and discontinuing ART (Baggaley et al. 2006)?
- ◆ What would be the effect of different strategies (reducing patient length of stay, and forcing staff and patients to use masks, or both) for controlling extensively drug-resistant TB (Basu et al. 2007)?

Types of mathematical models

In this section we give conceptual definitions of, and brief remarks on, some of the most important model types encountered in disease modelling. The list is far from a systematic review, and skirts controversy about type demarcation. Note that quite a few of these categories cut across each other—for example, compartmental models may be deterministic or stochastic, and they may be discrete or continuous, in any combination.

Individual-based models (also sometimes referred to as ‘agent-based’ models and ‘microsimulation’ models): in these, individual players (mainly people) exist as distinct entities able to experience changes in state (such as infection, relationships, fertility, and death). These models make it possible to implement complex rules, and to ask nuanced questions about important sequences of events, such as the ordering of condom use cessation, pregnancy, HIV exposure, declining health, and so on.

Compartmental models: these, the workhorses of applied mathematics, express a system in terms of ‘amounts’ (volumes, masses, or numbers and counts) of items or material in a number of categories, or ‘compartments’. They can range from models of water in a system of tanks, to money in portions of a portfolio, or people in regions, or population groups—such as infected, immune, risk groups, and so on.

In vivo models: models of biological processes within an individual, from cell and antigen life cycles to pharmacokinetic and pharmacodynamic models, are often referred to as ‘*in vivo*’ models. This categorization refers only to the real-world regime of which it is an analogue, namely biological processes, and does

not determine what kind of mathematical form the model takes (e.g. continuous versus discrete).

Population-level models: in contrast to biological-level (*in vivo*) models (earlier in this list), population-level models focus on a higher-level view. Usually this point is not explicitly noted, as most epidemiological models disregard complex biological details.

Discrete models (or discrete aspects of models): models with features which jump in discrete steps, such as time or other quantities expressing the state of the model world.

Continuous models (or aspects of models): models with features which vary continuously, being able, in principle, to take any value in some sensible range. This can readily apply to quantities, like population sizes, which are in reality discrete, without necessarily implying any inconsistencies. Note that it is not at all unusual for individual models simultaneously to conceive of some aspects continuously and others discretely—for example, discrete jumps in population states occurring against a continuous timeline and continuously varying risk factors.

Deterministic models: here the outcome is entirely determined by an ‘initial condition’ and the choice of dynamical rules and parameters. Mathematically, the model ‘output’ will be some sort of specification of the ‘model state’ over a range of times.

Stochastic models: here there is intrinsic randomness in the unfolding of continuous processes, or occurrence of events. Some such models are implicit in conventional data analysis, but these usually focus on modelling an experimental process which captures the random effects of sample selection and measurement error. We wish to draw attention to models where epidemiological processes are understood to involve chance, especially around transmission-related events. A fully fledged ‘stochastic model output’ will contain some sort of summary of possible ranges of outcomes, rather than merely example outputs which are ‘consistent with’, or ‘representative of’, the underlying rules. This can rapidly lead to great complexity and deep technical challenges, not to mention difficulties in presentation and interpretation. However, with the growth of computational power and the development of suitable programmes, stochastic models have increasing relevance and importance.

Static models: occasionally this term is applied to model worlds in which nothing at all happens, so that the model is just a static picture of a situation which may be useful in showing the instantaneous, or long enduring state of a system—such as a map of the world showing HIV prevalence estimates at a point in time. More typically, the term refers to a stable ‘context’ in which rules affecting individuals are static, and where we can still model individual life trajectories involving costs and benefits of health system interactions; here ‘static’ indicates the lack of accounting for impact (feedback) of factors like health system interventions on the overall context in which individuals will find themselves. Such a model can help focus on how individuals are expected to experience one or other health programme, implemented in a particular way and context which is readily specified, without entertaining complex dynamical questions about the inevitable evolution of the context itself.

Dynamical models: this can broadly refer to models in which parameters may change with time. However, a model may be called ‘dynamical’ when you wish to emphasize, for example, that an intervention which directly affects the well-being of people who receive it, can then potentially reduce infectious pressure; and that this is taken into account in computing the changing risk of infection over time. This may be crucial when long-term costs and benefits are estimated.

Some simple examples

This section is a demonstration of elementary models which capture the essence of dynamical modelling, with some conceptual digressions. The motivation for including it in this chapter is the subtextual message that modelling is really not something sinister or mystical, accessible only to a closed circle of initiates or specialists. Even though the illustrations are simple—and useful epidemiological models can be complex (though often need not be)—they form a valid basis for approaching most population dynamic models and, hence, disease transmission models. Readers with no prior modelling experience, but who are familiar with advanced high school mathematics, and have a willingness to suspend disbelief in their abilities, should be able to follow most, if not all, of the details of these examples. Those with some prior knowledge of elementary calculus but no experience of disease modelling should find here a foundation for a deeper reading of the modelling literature.

Modelling ‘exponential’ growth or decline

The notion of ‘exponential growth’ is one of the most important recurring themes of dynamical modelling—from pure sciences like physics to highly applied social science like population dynamics. It has little to do with the popular notion that something has ‘grown exponentially’, which often simply means that something has ‘grown enormously’. Technically, what is meant is that some quantity grows at a rate proportional to how large it currently is, with size and growth ever adjusting to maintain this relationship.

Question 1. Given a population of 1 million individuals, with individual mortality risk (m) of 0.001 per year, how many will be alive after 10 years?

Following our noses, we first build a discrete-time model, letting time, t , take discrete values 1, 2, 3, ... (years in our population-based example, but it could be days, seconds, and so forth). We let N_t denote the population after t years, and we assume that

- ◆ no births or immigration take place, and
- ◆ the same proportion, m , of the population N_t dies in each time step $[t, t+1]$.

The second point is really a foundational and widely recurring assumption—namely that the individual-level risk or probability of death can be directly taken, within each time step, to be the actual population proportion which dies. In truth, risks are expressions of averages (formally ‘expected values’) and for large populations, the actually realized proportions are usually very close to the appropriately defined average individual-level risk.

Throughout this section we will ignore models which consider how the ‘realized’ population dynamic ‘fluctuates’ around the

‘expected’ dynamic, and we will simply calculate the expected dynamic. This is a widely followed practice, which, firstly, is necessary in order to move ahead without drowning in technical complexity, and, secondly, is remarkably robust in many areas of science and engineering, including disease modelling. That is not to imply that random effects in population processes are irrelevant, merely that a large body of knowledge about dynamical processes can be developed by analysing the averages of these random effects. The study of variation around expected effects lies at the heart of statistics and formal data analysis.

The flipside, then, of the assumption about the proportion of deaths, m , per time step, is that a proportion $(1-m)$ of the population survives each year. Hence we have the following equations expressing the population in each year in terms of the population at the start:

$$N_1 = (1-m)N_0,$$

$$N_2 = (1-m)(1-m)N_0,$$

and so forth. These equations follow from the general expression governing the population dynamic, which gives the population 1 year later in terms of the population at time t :

$$N_{t+1} = (1-m)N_t.$$

It readily follows that, for any positive integer t , the population after t years is given by

$$N_t = (1-m)^t N_0. \quad (1)$$

Fig. 5.18.2 shows the decline of a population over successive years with the annual mortality increased substantially relative to our example, in order to show the effect more starkly in a small number of steps.

Even without mathematical analysis we might expect that, as the number of years grows indefinitely large (tends to infinity), the population becomes indefinitely small (tends to zero). This is

Fig. 5.18.2 (A) Exponential decline of a population, observed in regular time steps with a (percentage) attrition in each step. (B) Continuously observed exponential decline of a population or general quantity. A key property of exponential functions is that a simple rescaling, or inversion, of the axes, without any further shape adjustment, generates all possible exponential functions.

reflected in the formulae, in that the population size after t steps (years) is the original population size, multiplied by t copies (or t th power) of the factor $(1 - m)$, and that $(1 - m)$ is positive but less than one. A key concept in algebra and analysis is that powers of any number less than one can be made as close to zero as we want, by taking a high enough power. This property that, in each time step, the population sheds a number of members in proportion to how large the population was at the beginning of that time step, is the exponential decline of the population. According to the discrete model, then, the concrete answer to Question 1 is given, to the nearest whole number, by:

$$N_{10} = (1 - 0.001)^{10} 10^6 = (0.999)^{10} 10^6 = 990,044.9 = 990,045. \quad (2)$$

Now let time t vary continuously from zero to infinity. Assume again that no births or immigration take place but that there is a constant per capita mortality rate m . We will use the standard notation of calculus, but develop the argument intuitively rather than formally.

The fundamental concept in continuous-time modelling is to consider what happens as the time t advances by a very small increment dt . The nearly vacuous Fig. 5.18.3 is a sufficiently useful crutch for us to recommend it be drawn whenever continuous models are being developed. In reality, it becomes more and more likely that no notable events occur, as we consider ever smaller time windows, and the very idea of a time increment or window of size dt is of one that is small beyond all measurement and practical meaning. However, the crucial conceptual leap here is to recall that we are modelling not the actual number of events in some system realization, but rather the average number of events which are expected to occur in this time increment. As dt is intended to be tiny, the expected number of events is some tiny fraction, although the underlying real-world concept has no fractional population members or events. In continuously varying model worlds, populations vary smoothly in size and take on any numerical values which are needed to follow the locally applicable smooth dynamical rules.

Extending the argument of the large (or macroscopic) time step argument considered earlier in the discrete model, we declare that, between time t and time $t + dt$, there will be $mN(t)dt$ deaths. (Previously, we just used a time step of one unit, instead of giving it a named size, dt .) Thus we have a (negative) increment in the population, which we call dN . These two alternative expressions for the small difference in population, known as its ‘differential’, can be equated, yielding what is called a ‘differential equation’:

$$dN = -mN(t)dt,$$

which is usually written as:

$$\frac{dN}{dt} = -mN. \quad (3)$$

Fig. 5.18.3 The fundamental diagram of dynamical modelling in continuous time. By focusing on what happens during a small interval of time, between t and $t + dt$, we are enabled to derive differential equations whose solution will describe how the system evolves over time.

The meaning of dN/dt , known as a ‘derivative’, is, by analogy with the concept of gradient or slope, an expression for the rate of change of N with the passage of time. This equation can be solved (technically, ‘integrated’) by standard methods developed in any calculus course, to yield an expression for the population $N(t)$ after time t :

$$\begin{aligned} N(t) &= N(0)(e^{-m})^t \\ &= N(0)e^{-mt} \\ &= N(0)\left(\frac{1}{e^m}\right)^t. \end{aligned} \quad (4)$$

The symbol e denotes the ‘base of the natural logarithm’, a number (approximately 2.718) which, for analytical convenience, is the preferred base through which to define powers. Setting $N(0) = 10^6$, $m = 0.001$, $t = 10$, we can calculate the answer to Question 1 given by the continuous model, as follows, rounded to the nearest whole number:

$$N(10) = 10^6 e^{-0.001 \times 10} = 10^6 e^{-0.01} = 990,050. \quad (5)$$

This differs slightly from the answer given by the discrete model in Equation 2, and the respective solutions will diverge more as the number of years increases. This somewhat fine but important point is not an error per se in either method, or a sign of some fundamental incompatibility of approaches, and certainly not a reason for concern about the formal manipulations we have performed. In fact, it simply reflects our imprecise use of the fundamental notion of annual risk of death, a concept which is explored separately in the online appendix to this chapter, along with other fundamental modelling concepts. For now, we should note that the definition of a hazard rate like m needs to be carefully stated as applying to a particular period, such as a year. The value of m in Equation 3 in the continuous-time model is the intrinsic risk per unit time, and it is a theorem of calculus that this translates into the risk, $R(T)$ over a particular period, T , according to the expression:

$$R(T) = 1 - e^{-mT}. \quad (6)$$

Using the corresponding value for $1 - R(t)$, the probability of surviving for t years, in place of $(1 - m)^t$ in Equation 1, we can make the discrete-time model solution correspond exactly to the continuous-time model solution in Equation 4. (We note too, that $1 - m$ is an increasingly accurate approximation of the exponential function e^{-m} as m approaches zero.) In this simple case, the only difference is whether we intended to evaluate the discrete-time model for non-whole-numbered values of t .

The models we have just constructed also apply to a susceptible population being infected at a constant rate, which might then be called ‘force of infection’, ‘incidence’, or ‘hazard rate’. Similar problems may be framed in many other contexts, modelled by essentially the same equations: an infected population with constant rate of recovery, the mass of water remaining in a towel drying on a clothes line, the temperature (relative to room-temperature) of a cooling cup of coffee, the decaying mass of a radioactive substance.

Discrete versus continuous models

It is not necessary here to explore in detail how continuous and discrete-time models differ or correspond in less simple cases, but the following remarks may be helpful. Continuous-time models, though they may be daunting to people who are not comfortable with calculus, are in fact usually mathematically much simpler than discrete-time models. The rules which apply over an ‘infinitesimally’ small period of time, dt , do not need to be updated over this period of time, because the system itself accrues irrelevantly small (infinitesimal) changes in this interval. Hence, without much technical effort, we can usually solve for the state of the system at the end of an infinitesimal time step, relative to a specified initial state, by simply translating the rules of our model world from words into algebra. Thus we derive ‘differential equations’. Then, if we want to know how the system changes over a substantial period of time, we invoke the tools of calculus to ‘solve’ the differential equations. These ‘solutions’ are not values of populations at particular times, in the sense that ‘values’ are ‘solutions’ to the more familiar ‘algebraic’ equations. Solutions to differential equations are ‘functions’, that is, fully specified formal relations between population states and time.

Discrete models may require either extra sophistication or additional assumptions of convenience, in order for the fundamental time-step relations to be written down. These are called ‘difference equations’, and their solutions too are mathematical functions (of time) which are intended to be evaluated at discrete times. Sometimes these discrete time steps need to be taken seriously, and it will not be possible or sensible to simply read off the system state at non-whole-number times. For instance, it may be possible to build a year-on-year model of an insect population, which accounts for the net result of a brief breeding season with many births and deaths but does not attempt nor claim to describe the intermediate states when many eggs, larvae, and pupae are formed and eliminated. Similarly, seasonal models of human disease may not be intended to model the details of brief outbreaks, but merely account for net impact of typical outbreaks in terms of mortality, morbidity, vaccines used, accumulated immunity, and so forth.

Often, indeed usually, neither differential nor difference equations can be neatly solved with explicit formulae. Then it becomes necessary to use computational means to provide numerical approximations, graphical representations, and the like. These numerical methods form a mature and robust field of knowledge in their own right, and can deal routinely with most epidemiologically interesting models. On the other hand, sizeable challenges may arise with computational power and run-times required for in-depth investigations. Exploring many alternative scenarios in an attempt to ‘fit’ models to data, and exploring the sensitivity of outcomes to inputs and assumptions, may demand quite sophisticated use of data management technology and computer clusters.

To avoid proliferation of analysis, the remaining examples in this section will be demonstrated with the continuous formulation, chosen for its conceptual clarity and pedagogic value. The development of intuition about the applicability of calculus is a powerful problem solving capacity.

Question 2. What will happen to the population of Question 1, with death rate of 0.1 per cent per year, if there is immigration of individuals at an average rate of 200 per year?

Assume a constant per capita mortality rate m (a probability per unit time of death) as before, and a constant immigration rate b (a number of people coming in per unit time). In a small time increment dt , the change in population is given by:

$$dN = bdt - mNdt.$$

Hence the derivative (rate of change) is given by:

$$\frac{dN}{dt} = b - mN. \quad (7)$$

This ‘differential equation’ can be solved, by relatively elementary methods of calculus, to yield:

$$N(t) = \frac{b}{m} + \left(N(0) - \frac{b}{m} \right) e^{-mt}. \quad (8)$$

Note that the second term of the solution has the previously noted ‘exponential decline’ structure. Whatever value is taken for the initial population $N(0)$, this second term fades after a large period of time, so that, as time t tends to infinity, the population size tends to a constant equilibrium value, namely $N_E = b/m$, which in our case is 200,000. The key point is that this is the eventual state of the system no matter what the (positive) initial value was (see Fig. 5.18.4). A corollary to this is that, for our particular original population size to be maintained, an average influx of 1000 individuals per year would be required, since then $N_E = b/m = 1000/0.001 = 1,000,000$. Indeed, Equation 7 shows directly, without passing through the formalities of obtaining a solution, that the rate of change of the population will be zero when $N = b/m$. This idea of exploring the behaviour of dynamical (difference, or differential) equations in their own right, without working with potentially complicated solutions, is a normal, and very informative part of the investigation of the properties of model worlds.

The volume of water in a vertical-sided tank can be used as a helpful concrete mental image for this model, also making for a cheap and informative physical demonstration. Consider the water filling the tank to a level above a small outlet from which the rate of flow is proportional to the pressure at the outlet, and so to the height of the water level above the outlet, and hence also proportional to the volume $N(t)$ of water above the outlet (see Fig. 5.18.5). If the tap is shut, the water level will exponentially decay down to the level of the hole. If the tap produces a steady stream of water, the level in the tank will approach an equilibrium value at which the outflow matches the (fixed) inflow. In principle, the

Fig. 5.18.4 Question 2. Stable equilibrium.

Fig. 5.18.5 Flow diagram and water-tank model for population $N(t)$ at time t , with constant inflow rate b and variable outflow rate $mN(t)$. Question 1: No inflow, set $b = 0$. Question 2: Inflow or immigration rate b per year

tank may overflow if the hypothetical equilibrium water level is higher than the top of the tank.

This inflow–outflow model can be applied to the population of red blood cells in a human body. Bone marrow normally produces about 2×10^6 cells per second, or 1728×10^8 per day, while a nearly constant proportion of cells die daily. If we assume the body maintains an equilibrium population of about 2×10^{13} (20 trillion) red blood cells at any moment, that mortality rate can easily be calculated from our model.

Question 3. What will happen to the population of Question 1, with a per capita death rate of 0.001 per year, if there is no immigration, but a constant per capita birth rate of 0.004?

Once more we assume a constant per capita mortality rate m (again a probability per unit time of death) and constant per capita birth rate b , that is, a probability per unit time that an existing population member produces a new population member. This is a rather crude model of fertility, but the fertility rate b can be chosen to produce some reasonable dynamics. Certainly, a nuanced discussion of fertility, and other demographic processes like changing age structure of a country over time, cannot be aided by models lacking explicit age structure, but these kinds of complications are mainly about proliferation of detail, not mainly about new concepts. As ever, we have to understand what happens during a small time increment or time step of size dt . The change in population is given by:

$$dN = bNdt - mNdt, \quad (9)$$

hence the derivative (rate of change) is given by:

$$\frac{dN}{dt} = (b - m)N. \quad (10)$$

This can be solved to give:

$$N(t) = N(0)e^{(b-m)t}. \quad (11)$$

In Question 3 we proposed values of $m = 0.001$, $b = 0.004$, so that $N(t) = N(0)e^{0.0003t}$, which describes exponential growth. The model predicts exponential increase when $m < b$, a constant population when $m = b$, and exponential decline when $m > b$ (see Fig. 5.18.6). Exponential growth or decline is also called ‘geometric’ increase or decline. When there is exponential growth, it is easy to show that there is a fixed population ‘doubling time’, and in the case of exponential decline there is a fixed population ‘halving-time’, sometimes called the ‘half-life’.

Fig. 5.18.6 Question 3. Exponential growth/decline, and equilibrium.

That populations, even under much less simplistic assumptions, tend to increase geometrically was first observed and studied by Euler in the mid-eighteenth century, before being more famously explored by Thomas Malthus in 1798. Although exact exponential relations such as those presented here arise only under idealized conditions, their conceptual importance and wide applicability can hardly be overstated. With a technically small but far-reaching mathematical twist, they also form the basis of much modelling in pure science and engineering, including the study of oscillations and waves.

Susceptible–infectious compartmental models

The introduction of multiple health or disease states into our model worlds is naturally crucial to modelling disease transmission and progression. We will also need to expand our options for thinking about rates. Thus far, the populations in our example models have been allowed to:

- ♦ grow by fixed in- or out-flows (the immigration and mortality previously considered) or
- ♦ experience growth or decline processes scaled in proportion to the instantaneous population size (our fertility and mortality models).

Next, we consider the basic model of transmission, previously noted as the principle of mass action. Thus, the number of new infections occurring in a time window of duration dt is proportional to the number of infection-susceptible individuals, and also proportional to the number of infectious individuals, and hence proportional to the product of the two. The constant of proportionality can be understood to capture the probability per unit time of any one member of one group coming into contact with any one member of the other, and the ordinary probability (not per unit time) of such a contact leading to transmission of infection.

Question 4. How can we describe the prevalence of gonorrhoea in a closed sexually active population?

Let $S(t)$ and $I(t)$ denote the numbers of susceptible and infectious people at time t . Assume that individuals mix randomly, people are infectious as soon as they are infected, and they recover at a constant per capita rate r per day, after which they again become susceptible.

In a small increment of time, dt , the increments in numbers of susceptible and infectious individuals are:

$$dS = -\beta I(t)S(t)dt + rI(t)dt, \quad dI = \beta I(t)S(t)dt - rI(t)dt, \quad (12)$$

where β is the just noted mass action proportionality constant. Seen from the point of view of an individual, this indicates that the risk $\lambda(t)$ of infection at time t is given by $\beta I(t)$ (see also Fig. 5.18.7).

Fig. 5.18.7 Basic model of gonorrhoea transmission and recovery. Individuals move from the susceptible class to the infected or infectious class with incidence λ , arising dynamically from contacts with individuals in the infectious class according to the principle of mass action (perfectly random mixing), while they move in the opposite way through natural recovery. The dynamics are captured in Equation 12.

The system of differential equations describing the dynamics of $I(t)$ and $S(t)$ is:

$$\begin{aligned}\frac{dS}{dt} &= -\beta I(t)S(t) + rI(t), \\ \frac{dI}{dt} &= \beta I(t)S(t) - rI(t).\end{aligned}$$

These equations can be subjected to some instructive detailed analysis beyond our immediate scope. Hethcote and Yorke (1984) noted that the model has prevalence declining to zero for plausible estimates of the average partner change rate, the transmission probability per partnership, and the duration of infection. Indeed, certain types of models, such as those involving infections for which survival or cure confers immunity, or for which infection is incurable, generically predict that epidemics die out (potentially after temporarily rising to a peak) unless there is a sufficient source of new susceptible individuals. In this model, the cured individuals recover to be susceptible again, so, in principle, an endemic equilibrium might have been produced. As it was, the model led to a conundrum in the context of data on gonorrhoea as it could not reasonably explain the low, stable equilibrium prevalence in the United States in the 1980s.

Question 5. How can we model an observed low endemic prevalence of gonorrhoea in a closed sexually active population?

Hethcote and Yorke (1984) went on to build a further model (Fig. 5.18.8) in which they divided the sexually active population into two groups: low activity (the majority) and high activity—2 per cent of the population with higher partner change rate. They showed that with plausible estimates of the relevant parameters they could convincingly model the low gonorrhoea prevalence shown by the data. It is very common that simple first models of systems sensibly capture initial insights and data, but fail to reproduce crucial

Fig. 5.18.8 Model of gonorrhoea transmission with contact heterogeneity. The population is divided into a high- and low-activity class. Within each, individuals move from the susceptible class to the infected or infectious class with incidence λ , arising dynamically from contacts with individuals in the infectious class according to the principle of mass action. Meanwhile, individuals move in the opposite direction through natural recovery.

features which are known to arise in the real system. It is also very typical that one seeks to address this by identifying some important further refinement of population classes. This will require thinking about estimates of sub-population sizes, and details of contact and mixing rules. The work of Cooke, Hethcote, Nold and Yorke (Cooke and Yorke 1973; Yorke et al. 1978; Hethcote et al. 1982; Hethcote and Yorke 1984) highlighted the importance of incorporating in modelling both risk-heterogeneity and the class of asymptomatic individuals. The implications of their work helped to inform US control policy for sexually transmitted infections in the 1980s.

Other important classes of models

Our somewhat technical examples have only considered:

- ◆ Single populations experiencing in- and out-flows.
- ◆ Simple structured populations with susceptible and infected classes, and high or low contact tendencies.

Other key population structures which may be important to consider are:

- ◆ Gender.
- ◆ Age.
- ◆ Location.
- ◆ Relationship status.
- ◆ Finely resolved disease states such as exposed but clinically healthy and uninfected, or detailed viral and immunological markers.
- ◆ Treatment access and utilization.

Putting to one side the list of potential complications, we want to return to our opening remarks for this section. Model building and interpretation, while deserving care and attention, and benefiting from technical skill and experience, should not be seen as obscure activities left to the strange practices of a secret society.

The role of models is to formalize our understanding of, or hypotheses about, data and processes, so that we can tap into powerful tools developed by mathematicians over many years. This allows us to restate our thoughts about systems in an orderly fashion, demonstrating details of their internal workings, in the context of tough political and technical questions about investment in, and management of, public health systems.

Modelling as a process

In all good science there is an inescapable cycle of observation, hypothesis, and testing; of interactive theory-making and experimentation, reformulation of theory, and retesting. Ideally, mathematical modellers in the public health arena apply well-educated intuition to painstaking observations and interrogations of nature and human society. The aim is to frame the most interesting possible answers to important questions as quantitative hypotheses that can in principle be tested. This process entails choices about what kind of model to build, and the identification of parameters that can be varied, and perhaps later estimated, to determine specific model behaviour. Then there is the actual construction, logical analysis, and deduction within the model world; the interpretation, leading to reflections on, or predictions about, the real

world; the testing of predictions against data, recalibration, and retesting; and the possible revisiting of model design, statistical analysis, or the data itself. The modeller aims for validation (albeit provisional) and optimization of the model before reporting to peers and appropriate scientific and policy forums.

Basic principles of model selection

Following the quote from Einstein in the introduction, the first rule of modelling is: a model should be as simple as possible, provided it fits the data within the limits of accuracy. The nature and complexity of the model depends on the answers to some basic preliminary questions: what questions are we trying to answer? What scale are we working at? What data are available, and within what limits of accuracy? What degree of generality or precision is required? How soon are results needed?

Another rule of thumb for modellers is: even a simple model can be useful. Here ‘useful’ might mean yielding some qualitative insight, such as the basic shape of the prevalence graph (as in Ross’s malaria model), or the indispensability of heterogeneity of sexual activity in plausibly modelling sexually transmitted infections, as illustrated in the previous section. All models are imperfect by definition. Baran and Sweezy (1968) coming from the world of economics, capture well the philosophical essence of all good modelling, insisting that science progresses by building very partial models of reality. By selecting the decisive elements to gain a clear focus on, and abstracting from non-essentials, good models—while apparently unrealistic in a sense—offer us keys to understanding reality.

Comparing the utility of different models hinges on questions such as these: what is the purpose of this model? What can we get out of this model? Why should anybody believe its conclusions or predictions? What difference would it make if they did? On the need to balance simplicity and complexity in ecological models, Koella (1991) wrote:

On the one hand, the more variables...in a model the closer the predictions...agree with observations, simply because more degrees of freedom are involved. However, a close agreement between prediction and observation does not necessarily imply an agreement between the structure of the model and the biological processes. ... (Q)ualitative predictions of simple models may be more biologically meaningful than the precise quantitative predictions of complex models... (M)ore detailed models do not necessarily result in greater predictive power... (and)... more complex models may be less reliable than... simple (models). As one includes more detail... the number of assumptions about interactions increases exponentially... the probability of making a wrong and critical assumption increases rapidly, and... the predictive power... declines after some level of detail has been exceeded.

Choosing a model is often a delicate compromise. It is good modelling practice to allow the nature, quantity, and quality of the available data to inform the choice of model. The following examples serve to illustrate this principle. The archetypal wrong way to model a situation is to shoehorn the problem into a favoured model in which much prior effort has been invested. It is far better, as pioneered in the physical sciences, and applied successfully in epidemiology, to start with what is observed—the data—and ask specific pertinent questions that probe the data for patterns. The next step is to formulate hypotheses, or plausible narratives, that might help to make sense of the data and provide answers to the

questions. For asking the right questions, for arriving at fruitful hypotheses, as well as for any serious testing of the hypotheses, a prerequisite is relevant and reliable data—collected, scrutinized, and analysed with substantial biological, epidemiological, and statistical understanding. Only then can a relevant model be constructed. The mathematical modeller cannot contribute meaningfully in isolation, but the modeller’s work can be of great value in improving the subsequent design of trials and collection of relevant data, and in generating more refined questions; and so the cycle continues. Although the interactions are not strictly sequential or cyclical, we will formulate this modelling process very roughly below as consisting of four steps, illustrated by some typical fundamental questions, about measles, influenza, and HIV, thus developing further the discussion in the section ‘What kinds of questions are we trying to understand?’.

Step 1: asking questions

- Question 1. Why do measles epidemics oscillate?
- Question 2. Why do flu epidemics burn out but come back at rather irregular intervals?
- Question 3. Why is the prevalence of HIV declining rapidly in Zimbabwe, but not in Malawi, Zambia, or Botswana?
- Question 4. Why is HIV so much worse in southern Africa than anywhere else?
- Question 5. It seems that Cambodia now has only about 10,000 HIV-positive people with about 1000 new cases per year. How can we drive it to extinction?

Step 2: making hypotheses, learning to guess

Whether we are analysing a data set or building a model this cannot be done in a conceptual vacuum, so we need to decide what might be going on before we even start. Here are some ideas:

- 1. A measles epidemic seems to burn out rather rapidly but then re-establish itself at regular intervals. This could be because it is being driven by something external like climate. Or it could be something to do with the natural history of measles. Perhaps it has something to do with high-contact subgroups, associated with periodic school terms.
- 2. Once infected, a person is immune for the rest of that flu season, but there seems to be renewed susceptibility at the next flu season. Perhaps the host loses immunity, or perhaps the virus mutates.
- 3. Perhaps behavioural change, allied to educational levels and targeted educational programmes, is a significant factor in the different HIV dynamics observed in Zimbabwe, as also in Uganda.
- 4. Are people in southern Africa engaging in more sex, having more partners, and different kinds of partners, more concurrent partners, and more inter-generational sex than people in other countries? Is oscillating migration centred on the gold mines—an enduring legacy of apartheid—a significant driver of the epidemic?
- 5. In Cambodia there is the prospect of eliminating HIV completely. How can we best locate the few remaining cases? Are there useful parallels with smallpox or polio eradication?

The point about these ‘hypotheses’ is not that they should be right but only that they should be testable. If we can show that one particular explanation does not fit, we have made great progress by narrowing the possibilities.

Step 3: engaging with the biology, epidemiology, and statistics

Apart from high-level considerations, we need to learn as much as we can about the natural history of the disease and associated quantitative parameters: disease duration, case fatality, symptom duration, infectiousness, latent period, immunity (partial or complete), rates of increase (time), rates of spread (geography), susceptibility (by age, gender), periodicity, and geography. We then need to do some statistics to see if we can identify (or exclude) interesting relationships between variables.

1. Do measles epidemics occur annually in equatorial places where there is much less seasonality? What calendar correlations can be observed in countries with reliable data on measles outbreaks?
2. What trustworthy data can we access on the duration of flu epidemics and their frequency of occurrence? What’s known about phylogenetics and viral evolution? Is flu a zoonosis? That is to say, are there hosts for the virus other than man?
3. Have any studies explored correlations between HIV prevalence or incidence and significant differences in the backgrounds of various African population groups relating to history, geography, genetics, politics, religion, sociology, culture, migration, education, and health intervention? How can we explore the possible effects of behavioural change, whether as a consequence of educational programmes or perceived mortality?
4. What is the evidence that HIV is so much worse in southern Africa, and are there other places where it is equally severe? Can we identify factors that are peculiar to southern Africa? Oscillating migration? Sexual norms of behaviour?
5. We need to find very rare events. Should we do the equivalent of ring vaccination—when we find a person with HIV, test everyone in that person’s area, school, or social network? Should we do contact tracing—ask individuals to identify their sexual partners?

Step 4: choosing and building a mathematical model

It is usually the case that we do not have enough information to build a very detailed model, but starting from a very simple model may help us to focus our thoughts and identify those things that we need to understand if we are to model the transmission dynamics more accurately.

1. For measles, and for other viral and bacterial infections that commonly afflict children, such as rubella, mumps, pertussis, and diphtheria, a great deal is known. These infections have much in common from a modelling point of view: a direct route of transmission, lifelong immunity, and readily available techniques for detecting past or current infection. Measles periodicity might demand a model with positive feedback or a delay process to model the oscillations.

2. Since immunity is for life and we find that there are animal hosts (pigs and ducks), perhaps we should consider what is happening in the pigs and ducks. Does the virus mutate? Should we think about some kind of multispecies model?
3. We can build a model incorporating parameters describing delayed changes in sexual behaviour resulting from perceived HIV mortality. Can we, by varying parameters, achieve some kind of fit to known data on HIV prevalence, incidence, and mortality in Zimbabwe?
4. Data on sexual behaviour may reveal that this behaviour does not differ greatly among populations but that the network structure does. We might consider a network model.
5. For polio and smallpox the disease duration is rather short and this suggests that ring vaccination is a good idea; for HIV the disease duration is rather long so this suggests that contact tracing might be better. Think about network models and also about stochastic extinction.

Some important lessons may be drawn by would-be mathematical modellers, from these examples. First, to contribute significantly to infectious disease modelling, one must start with a specific, clearly defined question, and attain familiarity with the natural history of the disease. Second, if sufficient time and trouble is taken to understand the problem, the mathematical approach will often more or less suggest itself.

Principles of good practice in modelling

In order to promote good practice in epidemiological modelling in support of public health decision-making, of which a flip side is to facilitate interpretation of such models by non-modellers, a set of nine principles was recently distilled (Delva et al. 2012) out of a process involving the World Bank and the HIV Modelling Consortium (The HIV Modelling Consortium 2012). Though the immediate questions of that process were contextualized by the HIV epidemic, the principles themselves are completely general. We briefly outline them here, although a deeper engagement with these issues will benefit from a close reading of the full article and, even more, from a practice of habitual interaction with modellers.

Principle 1: clear rationale, scope, and objectives

A modelling study report should clarify, and appropriately refer to, the following three points, intrinsic to the interpretation of the study: (1) the precise questions the study aims to address; (2) justification for why epidemiological modelling is appropriate for the problem, rather than, or in addition to, some other study design (e.g. systematic review, meta-analysis, quasi-experimental design, randomized controlled trial); and (3) a profile of the intended readership. These three serve to ensure alignment of aims, model, results, and interpretation, and act as criteria for judging all modelling decisions.

Principle 2: explicit model structure and key features

A complete description of the model used in the analysis should be given (perhaps as an online technical appendix, including

computer code) to permit replication of findings and projections. This description should cover the basic structure (a flow diagram is helpful) and main features, cross-referenced to the scope and objectives, and a clear justification for choice of model type. The selection of model structure involves explicit choices about which factors (demographic, behavioural, biological, clinical, or epidemiological) to include and which to exclude, based on assumptions (which must be stated) or on research results (which must be quoted).

Principle 3: well-defined and justified model parameters

Among the assumptions to be explicitly listed in any modelling study are the nature and values of each parameter, for example, the annual population growth rate, or the probability of HIV transmission per sex act for an individual on ART. This listing should include, for each parameter: its name, the mathematical symbol (where relevant), its meaning in plain language, the value(s) assigned to it (a point estimate and range or confidence interval as appropriate), and a contextual justification for these values, whether the parameter is fitted in the model or is derived from another (referenced) source.

Principle 4: alignment of model output with data

The relative caution or confidence with which results of a model should be received depends on demonstrating the model's capacity to reproduce observed patterns. But of such 'validation', it has to be asked: were input parameters chosen to maximize the correspondence of outputs to data, or did these correspondences emerge naturally from choosing externally justified inputs? It is impressive when a model that has been fitted to a 'training' data set is shown to be capable of producing output in close correspondence with additional 'testing' data, especially when the second data set has independent origin or is markedly different. On the other hand, it may be quite unrealistic to expect a model to extend its predictive power to data emerging from a fundamentally different scenario, and the uncritical use of models that have not been calibrated to local data can mislead policymakers.

Sometimes a model's failure to fit data (without resorting to implausible assumptions about parameters) can lead to new scientific insights, through diagnosis of fundamental model limitations. And even when there are insufficient data to construct scenarios allowing credible predictions of future outcomes, modelling can still help to explore important questions such as what performance characteristics of a public health programme would be required for certain goals to be achieved.

Principle 5: clear presentation of results, including uncertainty

The presentation of model outputs, through judicious use of tables and graphs, warrants substantial investment of thought and effort, because the quantity of information in modern models (potentially run many times under carefully chosen conditions) easily becomes too vast for readers to absorb. It is the responsibility of modellers to highlight some particularly informative views of the results, in addition to providing all information for full replication (see Principle 2).

All assumptions, whether involving the structure of the model, the parameter estimates, or the data, will have uncertainties, and it is important to show how these propagate through to key model outputs (Blower and Dowlatbadi 1994). Uncertainty in a particular parameter may be benign—all credible assumptions give the same result—therefore meriting increased confidence in the model's use of this parameter. In other cases, different, superficially credible values for a parameter (or choices of model structure or interpretations of data) will lead to different results, perhaps not all plausible. For example, the simulated impact of an HIV intervention can be quite sensitive both to the assumed degree of heterogeneity in sexual behaviour and to the assumed patterns of sexual mixing, and the associated parameters are not easy to estimate even from good data.

Principle 6: exploration of model limitations

Model consumers may misunderstand the reductionist and minimalist approach of mathematical modelling, which (as explained earlier) proceeds by careful selection and abstraction of elements of reality requisite for answering specific questions. Effective dialogue can take place only if the modeller gives a full catalogue of model limitations alongside the results, so that model consumers are assisted to recognize both the weaknesses and the strengths of the model. On the other hand, consumers of models, looking for guidance in decision-making, should be alert to the possibility that the limitations are critical to their specific needs, and aware that open discussion by modellers of the limitations of their work is by no means a confession of ineptitude, or a sign of a model's irrelevance.

Principle 7: contextualization with other modelling studies

When different modelling groups appear to be addressing the same research question, but apply different model structures, with different assumptions, apparent conflicting results in the modelling literature may lead consumers of models to distrust their use in decision-making. To support an understanding of their differences, modelling results should always be set in the context of earlier relevant work, clarifying exactly where there is agreement and disagreement (Hankins et al. 2009; Kretzschmar et al. 2009; UNAIDS/WHO/SACEMA Expert Group et al. 2009; Hankins et al. 2011; Eaton et al. 2012).

Principle 8: application of epidemiological modelling to health economic analyses

In considering interventions, public health decision-makers generally seek to maximize cost-efficiency in some way. When cost-effectiveness, affordability, and returns on investments are of crucial interest, the most understandable and relevant modelling studies will be those that have integrated into cost-effectiveness analyses, providing outputs such as the number of incident infections or deaths averted, quality-adjusted life years gained, or disability-adjusted life years averted. Good examples appear in Vickerman et al. (2006), Anderson et al. (2009), Long et al. (2010), and Alistar et al. (2011), and guidelines have been developed for the production, submission, and review of health economic analyses by the *British Medical Journal* (Drummond et al. 1996). Conversely, it is important for those seeking guidance in health

economic analyses to critique the scenarios in which indicators have been calculated, and in particular to probe whether a suitable level of self-consistency has been applied to modelling the overall epidemiological dynamic, incorporating possible population-level feedback that is likely to be triggered through the proposed intervention itself, rather than a static view in which individual-level costs and effects are modelled in terms of an initial status quo.

Principle 9: clear language

For results to be considered by policymakers, it is important that modellers use language that supports effective communication. Such clarity is desirable at two distinct levels: the internal technical description of the model, and the intended real-world interpretation and application. Precision about model assumptions will help consumers assess the model on its own terms. Clarifying correspondence to real-world features and scenarios will help evaluate the impact of potential policy implications and interventions. Speaking as modellers, we particularly caution against overconfident statements like: ‘This modelling exercise shows that a consequence of the intervention will be...’

Conclusion

Modelling the transmission and control of infectious agents spans a very broad range of activities, from microscopic models of biological processes, to population-level projections of the consequences of large public health interventions. Stripping away layers of technical complexity, modelling is ultimately, when practised with discipline, little more than consistently clarifying relationships between data and assumptions. Often, modelling has been seen as a niche activity, but, encouragingly, there is increasing engagement and discourse with a range of disciplines, from clinical, laboratory, and social science to funding and policymaking. Modelling is becoming an important unifying discipline which enables disparate areas of knowledge and expertise to be brought to bear on key decisions in public health.

Public health surveillance

James W. Buehler and Ann Marie Kimball

Introduction to public health surveillance

Public health surveillance provides the epidemiological foundation for modern public health practice. The ongoing monitoring of disease or health trends within populations informs what public health actions are taken and reflects whether those actions are effective. Surveillance may involve monitoring of diseases and other health-related conditions as well as their antecedents, characteristics, and consequences. Surveillance can guide the local response to individual cases of disease or more broadly inform public health programmes and policies. A key function of surveillance is to identify circumstances that merit further public health scrutiny, such as groups or locations that are disproportionately affected or changes in disease occurrence or severity. Person, place, and time are the key epidemiological attributes of disease distribution in populations, and knowledge of these attributes afforded by surveillance allows targeting of public health programmes. General principles that underlie the practice of surveillance are essentially the same for all countries, regardless of economic development. Defining surveillance objectives depends on programme goals and on what information is needed, who needs it, and how it will be used. Desirable but potentially competing attributes of surveillance include completeness, timeliness, representativeness, high predictive value, acceptability, flexibility, simplicity, and low cost. Public health surveillance is conducted in many ways, depending on the nature of the health event under surveillance, the nature of healthcare and information infrastructures, the population involved, resources available, and information needs. The widespread and expanding use of the Internet, electronic media, communication technologies, and mobile computing have enabled innovations in public health surveillance that reach far beyond traditional methods. Surveillance systems should be periodically assessed to determine whether information needs are being fulfilled and whether the resources are being used effectively. Although surveillance methods were originally developed as part of efforts to control infectious diseases, basic concepts of surveillance have been applied to all areas of public health.

In many resource-poor countries, challenges to meeting needs for population health information are heightened and include potential tensions between the perspectives of external funders and in-country officials, between the interests of those responsible for disease-specific ‘categorical’ programmes and those interested in strengthening general surveillance infrastructures, and between advocates for using limited resources to strengthen

information capacities versus those who would focus spending to address urgent service needs. At the same time, recent innovations hold promise for improving surveillance in resource-poor settings, where precedents in developed countries that can impede innovation are absent or less established.

Definition

People who are responsible for protecting and promoting the health of populations need ongoing, timely, and reliable information about the health of the populations they serve. The term ‘surveillance’ encompasses the multiple processes that public health agencies employ to meet this need for information. Surveillance can include information about specific diseases or health risks or more general indicators of overall population health. As an integral part of public health practice, surveillance is an ongoing, systematic process of information collection, analysis, interpretation, visualization, dissemination, and connection to public health programmes (Thacker and Berkelman 1988). Surveillance systems are organized networks of people and activities dedicated to managing and maintaining surveillance for specific conditions. Surveillance systems can operate at various levels within countries, from local to national, or on a global scale.

In 1963, Langmuir established the modern concept of surveillance as ‘the continued watchfulness over the distribution and trends of incidence through the systematic collection, consolidation, and evaluation of morbidity and mortality reports and other relevant data’ together with timely and regular dissemination to those who ‘need to know’ (Langmuir 1963, pp. 182–183). In 1968, the twenty-first World Health Assembly described surveillance as the systematic collection and use of epidemiological information for the planning, implementation, and assessment of disease control; in short, surveillance implied ‘information for action’ (World Health Organization 1968). Over time, the scope and methods of surveillance have been adapted to meet the information needs of public health programmes that address a broad spectrum of infectious and non-infectious diseases and acute and chronic conditions. For brevity, the term ‘diseases’ or ‘conditions’ will be used as shorthand throughout this chapter for diseases, injuries, risk factors, and other health-related events that are the focus of public health programmes and surveillance systems.

Surveillance can include monitoring of the incidence, prevalence, antecedents (such as behavioural risks or hazardous exposures), characteristics, and outcomes of disease and other health conditions of public health importance. According to the US Centers for Disease Control and Prevention (CDC), a ‘public

health surveillance system is useful if it contributes to the prevention and control of adverse health-related events...and can be useful in contributing to [public health program] performance measures, including health indicators that are used in needs assessments and accountability systems' (CDC 2001). Surveillance should begin when there exists, or is likely to exist, a public health problem that merits attention, and it should be discontinued or revamped when the information it yields is no longer needed or useful.

Objectives of surveillance

The purpose of surveillance is to meet the needs of public health programmes for information about the health of the populations they serve (Box 5.19.1). These needs usually include a description of the temporal and geographical trends in the occurrence of a disease in a particular population. Questions addressed by surveillance can be summarized using epidemiological measures of time (when), place (where), person (who), and disease characteristics (what):

- ◆ **Time:** are disease trends upwards, downwards, or stable? Do downward trends coincide with interventions, such as the introduction of a vaccine, treatment, or prevention programme? Do upturns coincide with aggravating situations? Changes in trends might reflect the underlying health of populations or they might reflect changes in how surveillance is conducted or changes in medical or public concern about particular conditions. A key purpose of surveillance is to recognize changes in trends that might herald the onset of an outbreak or epidemic, prompting investigations to confirm the observed upturn in disease and, if so, identify the likely cause and guide interventions.
- ◆ **Place:** where is disease occurring or not occurring? Understanding geographic variations in incidence or prevalence can inform where investigations and interventions should be directed and can provide important clues to environmental, occupational, water- or food-borne, behavioural, or other risk factors. Alternatively, geographic variations might reflect differences in detection of disease resulting from variations in the availability, quality, or use of public health or healthcare services.
- ◆ **Person:** who is affected? Understanding the characteristics and commonalities of affected people, such as their age,

gender, occupation, race, ethnicity, habits, customs, or social or economic status, provides further insights into potential exposures or behaviours that can affect the risk of disease. Combined with information about the characteristics of the population at large, as from census data or population surveys, surveillance can provide critical insights into variations in the rates of disease among different groups. For example, in 1981, shortly after the disease later named acquired immunodeficiency syndrome (AIDS) was recognized and before the aetiological agent (human immunodeficiency virus (HIV)) was identified, by describing the sexual, blood-related, or perinatal exposures of affected people, surveillance combined with early epidemiological investigations helped to determine the infectious nature of the disease, identify probable modes of transmission, inform early prevention recommendations, and calm fears about the potential for widespread transmission through casual contact with affected people (Jaffe et al. 1983).

- ◆ **Disease characteristics:** what are the characteristics of disease, such as the clinical or laboratory manifestations, severity, and outcomes? For example, understanding the prevalence of the sensitivity or resistance of infectious agents to antimicrobial drugs is critical to informing healthcare and public health responses, and monitoring the prevalence of different microbe strains can be important for understanding the spread of different infectious or for vaccine development. Global influenza surveillance is used to anticipate which strains of influenza virus will be most prevalent during upcoming influenza seasons and to develop annual influenza vaccines (Cox et al. 1994). Differences in the spectrum or severity of disease among affected people might pinpoint differences among groups in genetic susceptibility, the co-occurrence of other illnesses, or access to healthcare.

Taken together, population-level measures of time, place, person, and disease characteristics can lead to an understanding of the impact of various diseases and insights into individual and social determinants of their occurrence. Surveillance might lead to hypotheses that can be tested in more definitive investigations and can identify individuals who could be enrolled in further epidemiological studies. In some instances, surveillance alone can provide compelling evidence of the impact of prevention programmes, such as the sharp decline in the incidence of a vaccine-preventable disease coincident with the widespread use of a new vaccine (Seward et al. 2002). In other situations, surveillance can contribute to evaluating the impact of interventions, but more detailed investigations are necessary to explain trends that are shaped by multiple factors. Low incidence or prevalence does not necessarily mean that certain diseases do not deserve public health attention, including continuation of surveillance, since this might reflect the impact of successful prevention efforts that must be sustained in order to prevent re-emergence.

Information on disease trends gained through surveillance, when combined with other information, can also be used to predict future disease trends. For example, with the ageing of the 'baby boom' population in countries such as the United States, projections of disease prevalence in the elderly, such as the anticipated prevalence and cost of dementia (Hurd et al. 2013), are garnering increased attention.

Box 5.19.1 Purposes of public health surveillance

To define public health priorities.

To characterize disease patterns by time, place, person, and disease characteristics.

To detect epidemics.

To suggest hypotheses for further investigation.

To identify cases for epidemiological research.

To guide and evaluate prevention and control programmes, including assessment of effectiveness and/or adverse consequences.

To facilitate planning, including projection of future trends and healthcare needs.

Setting priorities

An important use of surveillance is to help set public health priorities. In addition to recent measures of incidence or prevalence, other factors that can shape priority setting include likely future trends, the potential for public health or other interventions to have an impact, severity, disparities and attendant social justice concerns, and public interest. To the extent that surveillance data are used in priority setting, deliberations may give rise to concerns about surveillance methods, how surveillance data are queried and analysed, and the accuracy of estimates of disease impact. For example, even though mortality monitoring is the oldest form of surveillance and remains important in assessing the impact of different diseases (Thacker 2010), different agencies using mortality data may arrive at different conclusions, depending on the use of overall mortality measures, age-specific measures, or approaches that seek to integrate measures of mortality and wellness. Table 5.19.1 provides two estimates of the number of deaths (in millions) for leading causes of death globally in 2010, one from the Institute for Health Metrics and Evaluation (IHME) and another from the World Health Organization (WHO) (Liu 2000). Such estimates from different organizations rarely line up, and disparities in estimates can cause consternation among donors and national governments seeking to prioritize interventions.

In addition to using age-specific mortality measures, the impact of deaths among younger age groups can be further illuminated using a measure of years of potential life lost (cumulative years of life lost before a particular age such as 65 or 75 years). These measures can be further adjusted to account for the impact of diseases on the quality of life or disabilities. For example, in 1993, the World Bank Development Report, *Investing in Health*, adopted the approach of using disability-adjusted life years (DALYs) lost to consider not only the impact of premature death but also the impact on ill health or disability for specific diseases, in effect combining the mortality and morbidity into a single measure (World Bank 1993).

More recently, the IHME (Murray et al. 2012), experts convened by the WHO (2008), and groups focused on specific diseases have published estimates of DALYs to assess the impact of different

conditions. As with overall mortality estimates, DALYs estimates from different organizations rarely align.

Formal burden of disease estimates rely on diverse datasets and sophisticated modelling. Cross-sectional surveys such as the Demographic and Health Surveys (DHS) financed by the United States Agency for International Development (USAID) (USAID 2013), the Multiple Indicator Cluster Survey (MICS) sponsored by the United Nations International Children's Emergency Fund (UNICEF) (UNICEF 2013), and the Malaria Indicator Survey sponsored by USAID (Malaria Surveys 2013) along with special academic research studies provide country-specific data. Information on causes of death is enhanced by the inclusion of 'verbal autopsy' modules within some of the larger cross-sectional surveys. Data from these sources are then modelled to account for missing data points and to create locality- or country- and disease-specific estimates of DALYs.

Such efforts to estimate the impact of different diseases can be done periodically as data and the resources to analyse them become available, but this approach does not lend itself to frequent and ongoing monitoring where disease patterns are shifting because: (1) data quality is highly variable from different surveys or settings and often repurposed from its original collection goal; (2) cross-sectional survey information typically becomes available 1–2 years after surveys are completed; (3) estimates for very remote and information-poor geographic locations are often based on imputed data from neighbouring localities, and little 'ground truthing' is done to verify imputed data; and (4) assignment of causes of death, especially when based on verbal autopsies, is plagued with potential misclassification.

Establishing a surveillance system

Establishing a surveillance system requires a statement of objectives, definition of the disease or condition under surveillance, and implementation of procedures for collecting information (or obtaining information from existing sources), managing, analysing, visualizing, interpreting, and disseminating the information. In addition, as the number of surveillance systems increases, attention should be given to whether there are multiple systems

Table 5.19.1 Estimates of the global number of deaths, by cause, 2010, Institute of Health Metrics and Evaluation (IHME) and World Health Organization (WHO)

Cause of death	IHME	WHO
	Deaths (millions) (95% CI)	Deaths (millions) (95% CI)
Pneumonia/lower respiratory infections	0.847 (0.736–0.981)	1.396 (1.189–1.642)
Diarrhoeal diseases	0.666 (0.544–0.763)	0.801 (0.555–1.182)
Malaria	0.676 (0.445–1.002)	0.564 (0.432–0.709)
HIV/AIDS	0.126 (0.105–0.150)	0.159 (0.131–0.185)
Neonatal sepsis or meningitis	0.514 (0.318–0.841)	0.573 (0.388–0.789)
Total deaths in children <5 years of age	6.841 (6.439–7.302)	7.622 (no CI is given)

CI, confidence interval.

collecting information within a population and, if so, whether these systems collect common data elements and adhere to shared information standards. This is important to allow for information sharing across systems, to minimize duplication of effort, and to simplify the work of those who are asked to report to these systems. As surveillance becomes more automated and draws upon health information that is stored and transmitted electronically, adherence to information standards will become increasingly important. Attention should also be given to whether surveillance for a particular condition can be done similarly in different locations, increasing the likelihood that comparison of disease incidence or prevalence across multiple localities or countries is meaningful.

Surveillance systems are information loops, or cycles, that involve healthcare providers, public health agencies, and the public in a process of information collection, analysis and interpretation, and feedback. The cycle begins when events of public health concern occur and is completed when information about these events is made available and applied in public health programmes. This may involve multiple levels that should be specified in developing a surveillance system, ranging from the anticipated local response to individuals with cases of disease to the use of information aggregated from multiple localities to inform national policies. The delivery of information to constituents and policymakers (Langmuir 1963) is essential to the completion of the surveillance cycle. To the extent that surveillance data can be released without compromising privacy or confidentiality, they should be placed in the public domain to allow full use and benefits, with appropriate documentation.

Weaknesses in any part of the information chain can affect the entire surveillance process, and potential constraints should be anticipated. For example, when surveillance draws upon information arising from the use of healthcare services, surveillance will be affected by the availability and quality of those services, including laboratory and other diagnostic services (Berkelman et al. 1994) and by the accuracy with which diagnoses are recorded or coded.

No information resource is perfect, and establishing surveillance requires consideration of options, each with strengths and limitations, for how surveillance should be conducted at each step in the surveillance cycle. Having data that are complete and without error is desirable, but the effort required to obtain such data in a timely manner may not be feasible or sustainable. To assist in the design and evaluation of surveillance systems, the US CDC has identified a series of desirable but potentially conflicting attributes of surveillance. Deciding which of these attributes to prioritize will shape how surveillance is conducted:

- ◆ *Completeness*: ideally, surveillance data are complete, or stated in epidemiological terms, they have high *sensitivity*. Completeness will be a priority when it is essential to identify all people with a particular condition, such as a highly transmissible and severe infectious disease for which treatment is effective and can interrupt further transmission, or when it is important to have an accurate assessment of the impact of a particular condition.
- ◆ *Representativeness*: if surveillance is not complete, then ideally, it is representative of affected people within a population. Representativeness will be a priority when it is important to know where or among which groups to target interventions.

Representativeness can be affected by variations in reporting or by variable access to healthcare services. When surveillance depends on sampling of individuals or facilities, statistically defined sampling is ideal. But, rigorous sampling might not be feasible to implement, or response rates may be so low as to obviate the value of rigorous sampling. An alternative is convenience sampling, using informed judgement and best efforts to maximize representativeness in selecting sites to conduct surveillance.

- ◆ *Predictive value*: ideally, cases or reports represented in surveillance, indeed people with the disease or condition of interest, i.e. the data have a high positive predictive value. Predictive value is likely to be affected by the criteria used to define reporting requirements, resources available to make accurate diagnoses, the level of expertise and training of surveillance staff, or the nature of surveillance information resources. When diagnostic capacities are limited, surveillance often depends on syndromic criteria defined on the basis of symptoms or disease manifestations. Having the ability to conduct validations of syndromic diagnoses, at least in a sample of instances, can help to refine syndromic criteria or understand their limitations. The term 'predictive value' can also be used to characterize statistical alerts that disease trends have exceeded a predefined threshold indicating a possible disease outbreak. In this context, a high predictive value would mean that a high proportion of such alerts actually indicate the occurrence of outbreaks (CDC 2004).
- ◆ *Timeliness*: surveillance data need to be 'in time' to be useful, and timeliness depends on the intended use of the information. For example, a surveillance system that is aimed at detecting disease outbreaks as quickly as possible may need to monitor events within hours or a day of their occurrence. For disease where the use of prophylactic medications can prevent illness among contacts of affected people, surveillance must be sufficiently prompt to allow follow-up within the window of time that prophylaxis is likely to be effective. In contrast, for chronic diseases, such as cancer or cardiovascular disease trends, important trends unfold over a period of years, and annual data may be sufficient. Efforts to hasten the surveillance process are likely to come at the expense of other desirable attributes, such as completeness or predictive value. The metric of timeliness can be used to characterize the entire sequence of steps in the 'cycle of surveillance' as well as the promptness with which surveillance can identify aberrant disease trends.
- ◆ *Acceptability*: surveillance systems typically depend on the goodwill of many to sustain them over the long term. If reporting procedures are cumbersome, if the data are perceived as going into a 'black hole' without demonstrable use or value, if surveys take too long to administer, if information technologies that support surveillance are difficult to use, etc., then the *acceptability* and eventually the quality of surveillance will suffer. Public and political goodwill is also critical to sustaining funding and the necessary legal authorities to conduct surveillance. This requires that surveillance is conducted ethically, that confidentiality is protected, and that intrusions into the privacy of individuals are justified by the larger public good that arises from surveillance. Allowing public access to surveillance data (constrained as needed to protect confidentiality) can broaden the use of surveillance by researchers, students, journalists,

community advocates, and others and can enhance public support for surveillance.

- ♦ **Simplicity:** simplicity is desirable and can affect acceptability at each stage in the surveillance cycle. Like other measures, simplicity is a relative standard. For example, some users will prefer simple and quickly digestible reports that they can read quickly. Others will need to delve into the full complexity of surveillance in order to use it effectively, but simplifying access to the data and essential documentation would be desirable.
- ♦ **Flexibility:** information needs and the context in which surveillance occurs often changes over time, requiring flexibility to adapt to new circumstances. The epidemiology, diagnosis, or treatment of disease may evolve in ways that require changes in how surveillance is conducted. For example, in the decades following the initiation of AIDS surveillance in 1981 in the United States, the causative agent was identified, the treatment of HIV infection shifted from hospital to outpatient settings, immunological monitoring became part of routine patient care, an increasing proportion of infections among women and injection drug users was associated with changes in the spectrum of common disease manifestations, and the introduction of increasingly effective antiretroviral drugs altered the course of HIV infection. Taken together, these changes required multiple updates to the surveillance definition for AIDS (CDC 2008). In addition, disease coding schemes, such as the International Classification of Diseases, are periodically updated, and surveillance systems must adapt to these changes. Infrastructures established for the surveillance of one disease can be adapted to benefit surveillance of others, as illustrated by efforts to use capacities established for polio and measles surveillance to improve surveillance for meningitis and encephalitis in China, Bangladesh, and India (CDC 2012a).
- ♦ **Stability:** because most surveillance systems operate over long periods of time, stability in how surveillance is conducted is desirable to increase the likelihood that observed trends reflect the health of the monitored population and not fluctuations in how surveillance is conducted. This attribute can be at odds with flexibility. For example, while the 1993 revision to the surveillance definition for AIDS was necessary to accommodate changes in HIV/AIDS care and epidemiology, implementation of the new definition was associated with an abrupt increase in reported AIDS cases, requiring the use of complex mathematical approaches to discern underlying trends in the epidemic (Neal et al. 1997).
- ♦ **Interoperability:** although not one of the attributes considered in the CDC guidelines, interoperability of surveillance systems is becoming increasingly important as the number and automation of surveillance systems increases. If a system differs from others in how comparable information is categorized or coded or if it uses electronic information exchange standards that differ from others, then participants are likely to be frustrated by the extra effort required to accommodate multiple systems and/or to combine information from multiple systems. The term ‘interoperability’ describes the ability to combine or share information across multiple surveillance systems. As the use of electronic health records and electronic laboratory information systems expands, then consideration of interoperability extends

to the ability of public health surveillance systems to exchange information electronically with these clinical information systems. Similarly, if surveillance systems involve the use of mobile electronic devices to collect, store, or transmit surveillance information, those devices must be sufficiently compatible to allow for the desired exchange of information.

- ♦ The last attribute is *cost*, which can be measured in fiscal terms or in terms of the effort that is needed to sustain surveillance. Because public health and healthcare resources are limited, cost is often an important determinant of how surveillance is conducted and the need to minimize costs can constrain the ability to maximize other desirable attributes of surveillance.

Public health surveillance in under-resourced countries: special considerations

General principles that underlie the practice of surveillance are essentially the same for all countries. These include the steps of system design and the principle of collecting and using information for action. Of interest, the revised international health regulations, which were adopted by the WHO in May 2005 and came into force in June 2007, provide a powerful mandate to strengthen surveillance systems globally (Baker and Fidler 2006). However, information and other surveillance resources vary widely among countries.

Tracking disease trends, particularly infectious diseases, has been the main reason surveillance systems have been initiated in under-resourced countries. Surveillance data are also needed to establish rational public health priorities and to evaluate the impact of large-scale prevention and treatment programmes, such as those established for malaria, tuberculosis, and HIV/AIDS. Many infectious diseases and other conditions of public health import occur in settings with only rudimentary healthcare and few laboratory resources. With large-scale treatment programmes underway, the need for an adequate laboratory infrastructure has become even more critical, in large part to assure that the treatment is appropriate, that diagnoses are accurate, that microbes are not becoming resistant to therapies, or that viral or bacterial strains represented in vaccines are not being replaced by other strains. Lack of definitive diagnoses may hinder surveillance and response efforts as well as resulting in inappropriate therapy and adverse consequences, such as increases in drug resistance.

The success of surveillance depends on having sufficient resources, the simplicity of reporting procedures, personal rapport among people in the network, regular feedback, and the visibility of actions taken in response to case reports or analyses of surveillance data. For example, programmes to eradicate polio make extensive use of surveillance to monitor progress and focus efforts towards reaching their goals. A major accomplishment of the polio eradication programme has been to develop an integrated global virological surveillance network to track the genetic profile and transmission patterns of circulating polio viruses (Pallansch and Sandhu 2006). Eradication programmes must rely on such highly targeted surveillance, which becomes more important (and expensive) as eradication of the target disease approaches.

In many under-resourced countries, the absence of an effective vital event registration systems for births and deaths shapes how surveillance is conducted. Use of the verbal autopsy, based

on interviews to determine the cause of death, may assist in following mortality patterns in places without routine death registration (Kumar et al. 2006). The sensitivity of this approach in classifying causes of death may be lower for acute febrile conditions such as malaria, than for maternal deaths, injuries, tuberculosis, and AIDS. In addition, different techniques in conducting verbal autopsies may result in different sensitivities of classifications for specific conditions (Setel et al. 2006). A potentially simple and rapid alternative to such mortality surveillance is to monitor severe morbidity through periodic surveys of hospitals for the number of admissions attributed to particular conditions. Again, the success of such surveys is largely dependent on the accuracy of diagnoses.

Other sources of health information may include UNICEF, WHO, international conferences, non-governmental organizations, and population laboratories (e.g. the International Centre for Diarrhoeal Disease Research, Bangladesh). Although some health problems are similar in many under-resourced settings, relying on data from other countries or districts can often create major problems when there are large geographical differences in the incidence of specific conditions.

The design of surveillance systems must consider the security and safety of surveillance staff, geography and accessibility, population dispersion and mobility, type of health system, and literacy. Problems (more common but not unique to under-resourced countries) may include limited personnel available for public health, coincident operation of multiple surveillance systems within a target population, lack of laboratory capacity, and infrastructure and communications constraints (e.g. lack of equipment, supplies, or electrical power).

Solutions to address the lack of personnel for public health and prevention have included voluntary systems (using community health workers, traditional birth attendants, or village volunteers). More familiar solutions are public health training programmes designed to meet human resource gaps. Concerns about the cost-effectiveness of short-term training have resulted in establishing long-term programmes to build capacity within countries. Applied field epidemiology training programmes have been applauded for boosting the number of trained personnel (Cardenas et al. 2002).

Concurrently, the increase in availability of computers to analyse and transmit surveillance data and the decrease in the cost of such technology offer increased opportunities for surveillance. Epi Info™ is a freely available computer program designed to assist public health data management and analysis (CDC 2013a); this tool has been used successfully in both well-resourced and under-resourced countries, and is available in multiple languages. Epi Info™ and other information systems should be seen as tools to be used to provide data to policymakers and others to inform decisions that will improve health. The use of mobile phones and hand-held devices is proving useful in many areas. By leveraging the availability of mobile telephone networks and international telecommunication systems, few additional resources are needed to provide for collection of information and for two-way exchange of information needed for response.

Target population

The population under surveillance may be defined on the basis of where people live, work, attend school, consume water or food,

or use healthcare services. Alternatively, the population may be defined on the basis of where health events occur. For example, surveillance of traffic injuries aimed at identifying roadway hazards could include all injuries that occur in a target community, regardless of whether affected people live in that community.

In some cases, target populations for public health surveillance may be animals. For example, animal surveillance systems for West Nile virus and avian influenza have been developed, recognizing that these pathogens of concern to human health also infect animals and may alert public health authorities of potential transmission to humans.

Constituents of surveillance systems

Surveillance systems are likely to have many constituents, including healthcare providers, public health professionals, researchers at academic health centres, politicians, the media, the public, and others with diverse perspectives and uses for surveillance data. Because these diverse needs cannot always be satisfied, the primary or most important constituents should be identified as the system is established.

Nature of public health programmes

The objectives of surveillance systems will be shaped by the public health programmes they serve. For example, a programme to eradicate an infectious disease requires intensive surveillance in the later stages of the campaign that emphasizes identification of all people with the disease (Hinman and Hopkins 1998). In contrast, an educational programme to influence health-related behaviours may depend on a surveillance system that describes the practices of a sample of people in a community.

Health problems under surveillance

It is necessary to decide exactly what disease or health problem will be under surveillance. Surveillance may frequently be conducted for any of several points along a spectrum, ranging from exposure to an adverse outcome. It is important to consider which manifestations or stages of a disease should be under surveillance. For example, manifestations of ischaemic heart disease include angina pectoris, acute myocardial infarction, and (sudden) death, and precursors may include hypertension or behavioural risk factors such as tobacco use, unhealthy dietary habits, or lack of exercise.

Case definition

The case definition is fundamental to any surveillance system because it is the formal declaration of what is to be monitored. The case definition is primarily a criterion for determining who or what is to be counted but can also serve other objectives, such as providing a guide to clinicians for diagnoses. Where feasible, consistent use of case definitions across geographical areas permits comparison of disease rates. The case definition should be sufficiently inclusive (sensitive) to identify people who require public health attention or to monitor trends reliably but sufficiently exclusive (specific) for surveillance to have adequate predictive value.

Case definitions must be crafted so that they can be applied in a given surveillance context, reflecting the level of expertise of those who report and collect surveillance data and the extent of

information that is likely to be available. Surveillance case definitions may also be layered to include those with possible, suspected, presumptive, or confirmed diagnoses, depending on the urgency of need to respond to certain diseases before diagnoses are definitively established. For infectious diseases, confirmation of the diagnosis typically requires a positive laboratory test. But, if laboratory testing is not routinely available, syndromic criteria might be sufficient to guide treatments and to monitor disease trends. For example, in the United States, surveillance criteria for sexually transmitted diseases such as gonorrhoea or syphilis, incorporate both clinical and laboratory criteria (CDC 2011a), reflecting the routine availability of diagnostic testing. However, in many countries, routine access to such tests is not available, and syndrome-based criteria have been developed to treat and monitor conditions such as urethritis or cervical infection, based on prior assessments that included laboratory testing and informed presumptions regarding likely diagnoses and effective treatments (WHO 2003).

A similar range of possible case definitions also exists for surveillance systems that focus on adverse health exposures or risk behaviours. Body mass index (BMI), calculated using a person's weight and height, is commonly used in surveillance systems that track trends in the proportion of people who are obese or overweight. The use of self-reported height and weight, as in telephone surveys, or measured height and weight, which requires staff and equipment to perform the measurements, will affect the cost, coverage, and other attributes of surveillance in varying ways. BMI itself is a proxy measure for more direct measures of body fat that require weighing people underwater or sophisticated whole-body x-ray scans—measures that are unlikely to be feasible for surveillance purposes (CDC 2011b).

The flow of information

Surveillance may rely on data acquired explicitly for surveillance purposes or on secondary uses of data obtained from existing information sources. Regardless, there is a flow of information throughout the surveillance process, which should be planned.

Reporters

For surveillance systems that depend on reporting individual cases of disease or tabulations of disease counts, people responsible for reporting may be all or selected healthcare providers in a defined area, including laboratories. Reporters may also be asked to collect specimens needed by public health agencies for laboratory confirmation or characterization of specific diseases or exposures.

Data collection instruments

The desire to collect detailed information must be tempered by the need to limit data collection to information that can be reliably and consistently collected and used over the long term. Forms, questionnaires, or other data collection instruments that are too extensive will not be welcomed by those on whom the surveillance system must depend. While computerized systems may permit more detailed data collection, collecting large volumes of data may exceed the capacity of public health agencies to make effective use of those data. Standards for exchanging electronic health information are critical as healthcare information systems and public health surveillance systems become increasingly automated. In the United States, the Health Information Technology for Economic and Clinical Health (HITECH) Act in 2009

provides incentives for healthcare providers to adopt electronic health records and requires that doctors and hospitals use their electronic health record systems to report quality-of-care measures to government-sponsored healthcare insurance programmes for the elderly and poor and immunization service and certain disease data to state and local public health programmes, using national information standards (HealthIT.gov 2013).

Timing

Surveillance systems collect and provide data on a regular basis, ranging from daily to annually or, in some instances, every few years when surveillance depends on information from surveys that are conducted intermittently. This periodicity should be specified. For surveillance of a given disease or condition, acceptable intervals between the occurrence of events of interest and the eventual availability of reports from surveillance systems will depend on the nature of the targeted condition and how data are needed and used to inform public health actions.

Aggregation of data

Surveillance data may be in the form of individual patient records or aggregate counts and tabulations. In some instances, there may be a need at the local level to maintain records on individual people to direct follow-up services but for regional or national reports to be in the form of aggregate counts. Individual-level data permit more flexibility of analysis than aggregate data. This can be useful when routine analyses raise questions that require more detailed analyses.

Data transmission

The mode of data transmission will depend on both the need for timeliness and availability of resources. While reliance on postage of paper forms or facsimile transmission continues, there is growing use of telecommunications and the Internet to transmit surveillance information. In places where Internet access remains limited, the use of handheld mobile devices and mobile telephones for data collection and transmission is growing. In 2012, the World Bank estimated that three-quarters of the world's population have access to a mobile telephone, providing a relatively inexpensive and widely available technology to improve access to health information and public health surveillance (World Bank 2012).

Data management

Critical to the ongoing nature of surveillance is the management of surveillance data, including the maintenance of historical data and procedures for incorporating new information into surveillance databases. In particular, the following should be considered as part of data management procedures.

Updating records

Surveillance data often need to be updated. Information that was initially missing may become available; follow-up investigations may yield supplemental information; people initially classified as meeting or not meeting a case definition may be reclassified; errors may be identified and corrected; and duplicate case reports may be recognized and culled. One approach to handling these and other changes is to maintain both provisional and final records.

Selecting measures for time and place

A case report may include dates, such as those of the onset of disease, diagnosis, report to local health authorities, or report to

regional or national health authorities. Analyses of surveillance data may be based on the date of any of these events. However, if there are long delays between dates of diagnosis and report, analyses of trends based on date of diagnosis will be unreliable for the most recent periods. Similarly, surveillance data may be tabulated on the basis of the site of occurrence of the health event (e.g. the place of exposure, disease onset, or injury), the place of diagnosis, or place of residence. Classification of case events by place of residence of affected people allows for calculation of disease rates using census data.

Confidentiality/privacy

Because public health surveillance involves the collection and maintenance of information about the health of individuals, it represents a certain degree of government intrusion into personal health matters. This intrusion is minimized when data are collected anonymously or as aggregate counts and increased when data collection includes the names or other identifying information or when follow-up investigations are conducted that involve contacting affected people or reviewing medical records. In surveillance practice, the term ‘privacy’ describes expectations that others are not looking into our health status, and ‘confidentiality’ refers to the use and protection of health information held by public health agencies. The laws that authorize public health agencies to intrude on individual privacy for the benefit of both individuals and the larger community generally determine what information they are allowed to collect as well as requirements for protecting the confidentiality of public health records.

Preventing inappropriate disclosure of surveillance data is essential both to protect the privacy of people with reported cases of disease and to the trust of participants in the surveillance system. The protection of confidentiality begins with limiting collection of identifying information and transmission to a necessary minimum and includes ensuring the physical security of surveillance records, the discretion of surveillance staff, and legal safeguards. Uses of surveillance data should arise from a broad consensus of stakeholders in clinical medicine, public health, and the community (Fairchild et al. 2007).

Physical protection of records is accomplished by rules of conduct for people involved in the design, development, operation, or maintenance of any surveillance system. For automated surveillance systems, technical requirements for protecting data security should be part of information standards.

Users of data containing identifiers of individuals or establishments should be held to the minimum number deemed essential to perform public health functions. Those entrusted to use these data must be trained and accept responsibility to protect against inappropriate release. When surveillance data are reported, categories, such as those for age or place of residence, should be sufficiently broad to avoid inadvertent identification of an individual person or institution. The principle of making data as widely available as possible needs to be balanced with the protection of confidentiality. This can involve the development of public-access databases in which steps are taken to de-identify individual records. Even when efforts are made to de-identify records, data-use agreements may be necessary to prohibit efforts to re-identify data, which is increasingly possible using sophisticated analytic tools (Brownstein et al. 2006)

Initiating and maintaining participation

Whether required by law, voluntary, or (rarely) financially rewarded, reporting to or sharing information with public health takes time and effort. Even with automated electronic reporting, efforts are needed to install, validate, maintain, and periodically update the requisite information technologies. Minimizing the time and simplifying procedures for reporting is likely to increase adherence to reporting procedures. Dissemination of reports that demonstrate the usefulness of surveillance is likely to be a key to initiating and maintaining participation.

Public health laws provide the authority to conduct surveillance, and legal mandates that require that certain diseases or conditions be reported are an important approach to initiate and maintain reporting. In general, public health agencies have been reluctant to enforce these laws through penalties or fines because of concerns that such an approach would alienate healthcare providers—whose collaboration and partnership is essential not just for surveillance but for many public health interventions as well.

Organizational structure

Surveillance systems require an organizational structure that defines the roles and responsibilities of participants in all stages of the surveillance cycle, including participants at different levels of government (local, state, regional, national, or international). This includes articulation of procedures for alerting those responsible for prevention and control activities when surveillance data identify situations that merit further attention, such as an upturn in observed disease incidence that might herald the onset of an outbreak.

Types of surveillance systems and data

Historically, information sources for surveillance have fallen into two broad categories: information that arises from the use of healthcare service and population surveys. A third source is largely developmental: unstructured data that is culled from the Internet or other large electronic data repositories or from direct public participation in Internet-based social networks.

Surveillance might involve a mix of complementary sources that provide information on different facets of a disease. For example, influenza surveillance is often multifaceted and includes measures of morbidity (e.g. office or hospital emergency department visits for ‘influenza-like illness’ or hospitalizations among people with laboratory-confirmed influenza), mortality (e.g. deaths attributed to ‘pneumonia and influenza’), and laboratory-based indicators (e.g. viral isolates from participating laboratories where virus type, alignment with vaccine strains, or sensitivity to antiviral medications can be tested) (CDC 2012b).

Healthcare-based surveillance

Notification systems

Notifiable disease reporting is the approach traditionally used by public health programmes, based on laws or regulations that require reporting of selected diseases or conditions to public health departments. People or institutions responsible for reporting often include doctors, other healthcare providers, coroners

and medical examiners, laboratories, clinics, and hospitals. With the emergence of large, often commercial, laboratories that serve multiple providers across relatively large geographic areas, public health agencies are increasingly emphasizing laboratory-based reporting. This approach increases the timeliness and completeness of case reporting for diseases that require a laboratory test to diagnose. Because clinical information that accompanies specimens submitted to laboratories is often limited, however, follow-up with the providers who order laboratory tests or with patients themselves is often needed to complete case reporting (Ackers et al. 2000).

The overall completeness of notifiable disease surveillance depends on a succession of events: affected people must be sufficiently ill to seek healthcare, diagnostic tests are performed (which might not occur if patients are treated empirically), and positive results are reported. This approach may be relatively passive, meaning that public health staff do not reach out to healthcare providers to encourage reporting, or more active, meaning that public health staff may contact or visit providers to prompt reporting or assist in the reporting process. In general, more active approaches to surveillance will result in more complete and timely reporting. For example, in the late 1970s, a relatively large shigellosis outbreak in Washington, District of Columbia, United States, was not recognized by the health department's surveillance system because fewer than a third of outbreak-associated cases had been reported as required. A review of the surveillance system found that surveillance was not only incomplete but also not representative because reporting varied considerably among different facilities. In hindsight, adherence to reporting requirements lagged because the health department had taken a very passive approach and had done little to inform and remind local healthcare providers of their reporting requirements (Kimball et al. 1980).

Completeness of reporting may be affected for multiple other reasons: if patients and doctors seek to conceal the occurrence of diseases that carry a social stigma, if healthcare providers are unaware of regulations, or if interest in particular diseases is limited. Even if reporting is incomplete, temporal trends and geographic patterns can be determined as long as the proportion of cases detected remains consistent over time and across geographical areas. Conversely, lack of representativeness and heterogeneity of reporting further limit the usefulness of incomplete data (Lowndes et al. 2004).

Example: notifiable disease surveillance in China

The China Infectious Disease Automated-alert and Response System (CIDARS) is an extension of the nationwide electronic system for notifiable disease reporting that was initiated in 2004 following the severe acute respiratory system (SARS) outbreak. The system focuses on 39 infectious diseases or syndromes that clinicians are required to report to the Ministry of Health. CIDARS added a formal process for analysis and follow-up that specified statistical thresholds for prompting alerts, based on the number of cases relative to historical precedents or temporal-spatial clustering; procedures for notifying responsible local officials via mobile telephone when those thresholds were exceeded within a locality; responsibility for preliminary assessments and, if indicated, more definitive field investigations; and responsibility for documenting and reporting the results of those assessments and investigations.

In an initial evaluation of CIDARS conducted in a sample of ten provinces, for nine relatively rare but potentially severe infections, 308 alerts were identified during a 2-year period in 2008–2010, of which 69 (22 per cent) merited a field investigation, leading to detection of nine cholera outbreaks. For other more common but less severe diseases, there were more than 100,000 statistical alerts, of which 1.4 per cent were deemed to merit further attention, leading to detection of 167 disease outbreaks (Yan et al. 2012).

Healthcare provider networks

Networks of healthcare providers have been organized for several decades, primarily to gather information on selected health events. Most have been organized by practising doctors on a voluntary basis; in many European countries, these networks have formed firm relationships with both public health authorities and academic centres. The strengths of sentinel provider systems include the commitment of the participants, the possibility of collecting longitudinal data, the flexibility to address a changing set of conditions, and the potential to conduct focused studies of the incidence, prevalence, care, or outcomes of various conditions, typically in primary care settings (Fleming et al. 2003). The main limitation of this type of system is that the population served by participating doctors may not be representative of the population.

Laboratory surveillance

Laboratory surveillance may be conducted as part of a notifiable diseases system, sentinel surveillance system, or other system. In addition to supporting routine case reporting, laboratory-based surveillance can allow for the use of molecular epidemiological tools, more detailed evaluation of microbe strains or types, and monitoring of drug sensitivity. The use of molecular tools to enhance surveillance of pathogens is growing in many countries to facilitate outbreak detection, especially in situations where disease is associated with widely distributed food products, where the number of cases of illness due to a particular infection is insufficient to prompt attention, but where epidemiological linkage of geographically disparate cases allows detection of distinctive outbreak-associated pathogen strains. In the United States, PulseNet is a network of public health laboratories that performs DNA 'fingerprinting' on bacteria that may be foodborne (Swaminathan et al. 2001). The network permits rapid comparison of these 'fingerprint' patterns through an electronic database and has detected multiple outbreaks that likely would have been otherwise unrecognized. For example, in 2008–2009, PulseNet detected and enabled tracking of an outbreak of salmonellosis associated with contaminated peanut butter with over 500 cases of illness detected in 43 states (CDC 2009). Molecular methods are also increasingly applied in surveillance of the HIV epidemic. For example, surveillance systems in Canada (Jayaraman et al. 2006) routinely characterize newly diagnosed HIV infections with respect to the HIV subtype.

Disease registries

Registries are comprehensive longitudinal listings of people with particular conditions. They often include detailed information about diagnostic classification, treatment, and outcome. Registries were initially established primarily for epidemiological research on individual diseases or conditions to develop

aetiological hypotheses and to identify cases for further research (Weddell 1973). Registries have also been used to ensure the provision of appropriate care and to evaluate changing patterns of medical care; unlike other disease information systems, they cut across the different levels of severity of illness and may provide information over time about individual people. Registries can also be valuable for monitoring disease incidence and distribution.

To focus on selected diseases or conditions, registries often develop a constituency that promotes participation and reporting. Most registries rely on numerous sources of data for case detection including, but not limited to, hospitals, laboratories, and death records; few registries rely primarily on doctor notification.

Example: birth defects

Surveillance for birth defects was first initiated in response to the thalidomide tragedy in the late 1950s and early 1960s; registries were established to provide reliable baseline rates for specific birth defects and to detect increases in the prevalence of birth defects as a means to identifying human teratogens. The CDC has conducted birth defects surveillance in metropolitan Atlanta, Georgia, United States, since 1967 by using multiple sources of ascertainment of all serious birth defects observed in stillborn and liveborn infants and recognized by signs and symptoms apparent in the first year of life (Correa-Villasenor et al. 2003).

The International Clearinghouse for Birth Defects Surveillance and Research consists of 40 registries globally (Botto et al. 2006). The International Clearinghouse conducts a spectrum of surveillance activities that includes monitoring of selected conditions, and the exchange of information about birth defects clusters under investigation, findings of unpublished studies, and rumours about the occurrence of birth defects. Clearinghouse participants work at the intersection of surveillance and research in their assessment of the potential teratogenicity of first-trimester use of medications.

Healthcare information systems

Surveillance systems often depend on existing health data collection systems; these systems may be either integral to surveillance or serve as an adjunct to surveillance for specific diseases or conditions. Examples include use of hospital discharge databases and insurance claims data. Because these databases are often established for monitoring the use of healthcare services or to support billing or payment for healthcare, they allow not only for the assessment of the prevalence of multiple diseases but also for assessment of their impact on healthcare use and costs. For example, as part of a multifaceted approach to diabetes surveillance, the CDC uses data from a national hospital discharge database to track lower extremity amputations among people with diabetes—a severe complication arising from long-term inadequate management of diabetes (CDC 2012c).

The advantage of this approach is that it involves use of information systems that have been previously established for other purposes and can be tapped for surveillance applications for relatively little additional expense. In addition, these information systems often represent very large numbers of people. The main limitation is that diagnoses may be inaccurately or variably recorded or coded. For example, workers' compensation claims have been useful for surveillance of occupational injuries and illnesses in specific geographical locales. However, because regulations governing reporting of such events differ among jurisdictions, data

derived from these systems in different locations cannot easily be compared and the incidence or prevalence of various conditions is likely to be underestimated (Fan et al. 2006).

In areas where a growing number of healthcare providers are using electronic health records, local or regional organizations are being developed to foster automated exchange of information from patients' medical records. The primary aim of these efforts is to facilitate providers' access to information about their patients, including information stored in other providers' record systems. Ideally, this can lead to improved efficiency of health care by reducing the time needed for retrieving patients' information from other providers, reduce medical errors, and reduce redundant use of diagnostic tests. From the public health perspective, these 'health information exchanges' provide a focal point for obtaining surveillance information within communities and for providing feedback to clinicians (Public Health Informatics Institute 2005).

A variation on the use of health information systems is the creation of 'distributed' networks of healthcare providers or insurers who maintain electronic healthcare or billing records. In these systems, participating institutions or organizations agree to extract and maintain selected data on an ongoing basis. Rather than share these data in a centralized repository, participating institutions agree to analyse their data and share the results using standardized queries. Examples include the Vaccine Safety DataLink system coordinated by the CDC to monitor and assess potential adverse reactions to vaccines and the Sentinel network supported by the US Food and Drug Administration to characterize adverse reactions to medications. Because these systems comprise very large numbers of patients, they can be used to track relatively rare events (DeStefano 2001; Behrman et al. 2011).

Vital statistics

In countries with well-established vital event registration systems, monitoring trends for various causes of death is a long-standing part of surveillance for life-threatening conditions. Despite the well-recognized limitations in how causes of death are classified on death certificates, monitoring cause-specific mortality trends overall and by age, gender, and geographic location provides a useful, broad-brush picture of the impact and trends for multiple conditions.

There is frequently a lengthy interval between death and collection and analysis of death certificates, which may make such vital statistics less useful for surveillance purposes when more current data are needed. However, summary vital data can be rapidly collected. For example, weekly reporting of deaths from 122 cities to the CDC has been integral to the surveillance of influenza epidemics in the United States (Fig. 5.19.1), providing an indication of the timing and severity of annual seasonal influenza relative to historical norms (Choi and Thacker 1981; CDC 2009).

Medical examiner and coroner reports

For more detailed descriptions of the circumstances surrounding deaths (including autopsy reports, toxicology studies, and police reports), medical examiner and coroner records may be useful. These reports are typically representative of unexpected or medically unattended deaths or deaths caused by intentional and unintentional injuries and have been used for surveillance of such conditions as heatwave-related mortality and alcohol-related

Fig. 5.19.1 Percentage of deaths attributed to pneumonia and influenza (P&I) reported by the 122 Cities Mortality Reporting System, by week and year—United States, 2008–2013.

Reproduced from *FluView, 2013–2014 Influenza Season Week 3 ending January 18, 2014*, Pneumonia and Influenza (P&I) Mortality Surveillance, available from <http://www.cdc.gov/flu/weekly/#S2>.

injuries. Systematic necropsy examinations have also been useful in ascertaining the contribution of tuberculosis to mortality of HIV-infected individuals in West Africa. Antibody determinations performed on postmortem medical examiner samples may be useful for estimating population prevalence of infectious diseases (e.g. dengue) (Rigau-Perez et al. 2006).

Syndromic surveillance

A growing number of public health agencies have been prompted by concerns about the threat of bioterrorism to invest in automated ‘syndromic surveillance’ to detect epidemics more quickly than possible using traditional approaches (CDC 2004; Mandl et al. 2004). This involves monitoring trends in healthcare use for relatively non-specific syndromes (e.g. febrile respiratory illness or gastrointestinal symptoms) or other manifestations of illness (e.g. medication purchases, work or school absenteeism) that may be apparent and can be monitored before diagnoses are established. Because these systems emphasize timeliness of the entire surveillance process, often enabling tracking of events within a day or less of their occurrence, they generally rely on data from electronic health information systems. These systems use automated methods to harvest electronically stored data, apply statistical tools to detect aberrant trends, and develop visual displays of geospatial disease trends. Despite this emphasis on automation, these systems still require human judgement to interpret reports and determine what level of further assessment or response is warranted when statistical alerts are generated.

Population health surveys

Behavioural data can be collected from samples of the population at large, from populations at particular risk for the health condition of interest, and from populations affected by the health condition of interest (Davy 2006). When conducted in person, objective

measures of health can also be obtained, such as measurements of height, weight, blood pressure, or collection of specimens for laboratory testing. Population-wide household surveys, such as the National Health Interview Survey in the United States (CDC 2013b) or the General Household Survey in England and Wales (Twigg 1999), have provided information on personal health practices such as alcohol use and smoking, disabilities, and doctor encounters.

In countries where most residents have telephones, telephone interviews have the advantage of lower cost per interview, allowing for wider geographic coverage and more local estimation of the prevalence of various health indicators. For example, in the United States, all states conduct the Behavioral Risk Factor Surveillance System (BRFSS) to monitor a spectrum of health-related behaviours at the state, and in many instances local level. The BRFSS, like all telephone-based surveys, has had to adapt to the declining use of landline telephones and the increasing use of mobile telephones, trends that have varied among demographic groups within the population (CDC 2013c).

Inclusion of behavioural measures has been advocated by the WHO for HIV and sexually transmitted infection surveillance programmes. Increasingly, demographic and health surveys are conducted to include both behavioural and biological measures, and to use sampling methods that provide representative data on a population level (Kenya Central Bureau of Statistics et al. 2004).

Surveys of populations at special risk may also play an important role in guiding public health response. Such systems may be relatively simple, in the form of episodic surveys of convenience samples (e.g. episodic convenience samples of men who have sex with men attending gay bars in Scotland) (Williamson et al. 2006) or may be formalized as ongoing surveillance systems. Such surveys can provide data on levels of risk behaviours, on adoption of desired preventive behaviours, and on exposure to public health prevention messages.

Unstructured data

Internet-based approaches to surveillance

The widespread use of the Internet and electronic media has led to innovations in population health monitoring that reach far beyond traditional surveillance methods. In 1994, the International Society for Infectious Diseases launched the Program for Monitoring Emerging Diseases (ProMed), which allowed individuals to post reports and updates on disease events on a public-access Internet site, with a moderator assuring the professionalism of the website. Information posted on ProMed includes alerts, reports of epidemics, and local observer reports, with over 30,000 subscribers worldwide (Madoff and Woodall 2005). For example, the earliest public notice of the outbreak later known as SARS was in the form of a query posted on ProMed in early 2003 by a physician who learned from an acquaintance of widespread severe respiratory illness in Guangzhou, China. This report and other updates to ProMed alerted the global public health community to this epidemic and played a key role in charting its course of spread to multiple countries (Yu and Madoff 2004).

The Global Public Health Intelligence Network (GPHIN) is managed by the Public Health Agency of Canada and is geared to providing early warning for potential threats to public health worldwide. GPHIN uses an ongoing, automated process to monitor online media reports in six languages worldwide for early indicators of events such as disease outbreaks, natural disasters, food or water contamination, potential biological or chemical terrorism, and other threats. GPHIN operates 24 hours a day, 7 days a week in 'near real time.' Access to GPHIN is limited to agencies determined to have a legitimate public health mandate, as determined by the WHO and Health Canada (Public Health Agency of Canada, 2013). The Google.org Flu Trends monitors trends in Internet searches using terms that have been observed to correlate with influenza activity. While this approach yields trends that parallel other indicators of influenza-like illness, its public health application is yet to be determined (Valdivia et al. 2010).

The growing use of the Internet, including use of mobile phones that provide mobile Internet access, is enabling a form of public 'participatory epidemiology' or 'crowd sourcing' where interested members of the public or members of online communities interested in specific health problems are encouraged to post reports of illness or disease outbreaks. The application of such utilities and services is an area of ongoing development and evaluation (Freifeld et al. 2010).

Analysis of surveillance data

Uses of surveillance data begin with descriptive analyses according to the basic epidemiological parameters of time, place, and person, including the use of standard tests for statistical significance. Typically, public health surveillance data are completed, summarized, and reported over specified time intervals (days, weeks, months, or years) and for specific geopolitical jurisdictions (cities, counties, states, provinces, nations, etc.). Incidence or prevalence rates can be calculated using various population denominators, typically census data, and comparisons of rates over time or across geographic areas should be adjusted using standard methods to account for differences in population characteristics, such as differences in the age distribution of populations. The use of maps or graphics is common to illuminate differences in disease incidence

or prevalence by time, place, or personal characteristics such as age or gender.

Analyses of trends are generally designed to determine whether current or recent levels of disease differ from levels that would be expected based on historical precedent, which may be defined over a period of years to days, depending on the availability of historical data and the epidemiology of different diseases or conditions. Detection of epidemics or evaluation of suspected epidemics is a key function of surveillance. Nonetheless, many epidemics are first recognized by astute healthcare providers who observe an increase in disease occurrence, instead of being detected by surveillance systems, because the cycle of surveillance has not had time to detect an upturn. Even in such instances, however, surveillance can be useful to help assess whether recently observed cases of disease exceed expected levels. Surveillance is most likely to provide the initial recognition of potential epidemics in situations where cases are occurring over a sufficiently large geographic area or time period so that the increase would not be apparent to individual practitioners.

The key to discerning whether observed trends are in excess of expected trends is excluding the possibility of random variations or 'noise' in observed disease levels. One approach to resolving this dilemma is to employ various techniques to 'smooth' the data, especially for graphic displays of temporal trends (Devine and Parrish 1998), including the use of moving averages or the aggregation of data points into longer but still relevant time intervals (e.g. by week instead of by day or by month instead of by week). A spectrum of advanced analytic techniques for evaluating trends in surveillance data has evolved to model various types of historical trends, such as seasonal variations or long-term secular trends, to estimate predicted or expected levels of disease based on those trends, and to determine whether observed levels are statistically different from expected levels (Brookmeyer and Stroup 2003). The use of geographic information systems extends the traditional use of maps to display surveillance data by allowing for analyses that allow geospatial assessment of disease and locations of risk exposures or preventive or therapeutic services (Waller and Gotway 2004). Recognition of clusters of disease is common but often difficult to distinguish from random variation, giving rise to various statistical techniques to detect and characterize clusters (Kulldorff 1997). The increasing automation of the surveillance process, especially for systems of syndromic surveillance that track daily trends in disease and seek to detect changes in disease trends quickly, has spawned the development of statistical methods and computer software algorithms for automatic trend aberration detection, including techniques that are derived from cluster detection and industrial quality control methods (Burkom 2007).

Regardless of whether analyses involve straightforward descriptive statistics or advance modelling techniques, any analyses of surveillance data must take into account potential limitations of the data, including variations in their completeness, representativeness, timeliness, or data quality over time or among different locations.

Linkage of surveillance data to other information sources

Given the complexity of establishing new data and information systems, there is increasing interest in the combination of existing databases for surveillance purposes. This allows the combination

of information about individual case-patients from multiple sources. For example, linkage of birth certificates (which include the birth weight and information on other infant or maternal characteristics) and death certificates (which include information on the age and cause of death) allows determination of neonatal or postneonatal deaths rates for infants in different birth-weight or gestational age groups (Buehler et al. 2000). Linkage of HIV and tuberculosis records enables surveillance for the co-occurrence of these two infections (Ahmed et al. 2007).

Techniques involved in data linkage are based on comparing records from different information systems, assessing the likelihood that records from two different sources represent the same individual, and combining the data for those individuals whose records match (Clark 2004). In using linked record systems, assessments should be done to determine what proportion of linked records do not actually represent the same individual and, conversely, what proportion of records should have been but were not correctly linked.

Dissemination of surveillance information

Communication of surveillance data is an essential step in the surveillance chain. Appropriate feedback must be given to those providing the data, such as analyses that allow them to compare their experience to that of the community at large and other reports that enable them to see the value of the information resource to which they contributed. When appropriate, people or institutions providing the data should be credited for their contributions and acknowledged. Public health professionals, policymakers, or others who may be responsible for taking action or setting the direction of public health programmes in response to surveillance data must receive the information that they need from the surveillance system on a timely basis and in an appropriate format for their use. In addition, these data should be available as widely as possible to all who may be interested in analysis and interpretation of these data. Websites are increasingly used to disseminate surveillance data as with the US CDC's *Morbidity and Mortality Weekly Report* (<http://www.cdc.gov/MMWR>), the WHO's *Weekly Epidemiological Record* (<http://www.who.int/wer>), and the European *Eurosurveillance* (<http://www.eurosurveillance.org/>).

The data must be provided on a regular basis, with the frequency of surveillance reports commensurate with the nature of the surveillance system, the characteristics of the disease under surveillance, and information needs. To improve the timeliness of surveillance data, provisional or preliminary data may be released, with appropriate caveats, in advance of completion of more definitive reports.

The format for dissemination varies with the target audience; a creative design will help to make the information stand apart from other documents and receive greater attention. Most policymakers and clinicians would prefer to see the data interpreted using graphics that provide a quick visual image that highlights key observations, accompanied by an abbreviated summary text. The important role that graphs and maps can play in visually decoding large quantities of data has been clearly demonstrated, with graphic displays giving the reader an understanding of large and complex datasets not conveyed easily in other ways (Tukey

1977; Tufte 1983). In contrast, many epidemiologists and other scientists will find access to more detailed data to be most useful.

Evaluation of surveillance systems

Surveillance systems should be periodically evaluated to ensure that important public health problems are under surveillance, that the information provided is useful, and that resources dedicated to surveillance are being used wisely. Such evaluations may include a mix of quantitative and qualitative assessments (CDC 2001, 2004; Silk and Berkelman 2005; Buehler et al. 2009). Evaluation may also be considered in a broader strategy of continuous quality assurance (Krause 2006). Reflecting the steps that are taken in establishing a surveillance system, an evaluation of a surveillance system should include a review of its objectives, a detailed description of its operation, an assessment of its performance using the surveillance attributes as a guide, and recommendations.

Conclusion

Public health surveillance has historically galvanized and guided prevention and control programmes for infectious diseases, ranging from smallpox eradication, immunization campaigns to prevent childhood diseases, programmes to prevent HIV infection and AIDS, and responses to emergent diseases such as SARS or pandemic influenza. Surveillance has also taken on increased visibility and importance in evaluating and guiding prevention and control efforts for a broad spectrum of non-infectious diseases and conditions. Surveillance provides a stimulus to keep prevention and control activities moving in the right direction, guiding the response to individual cases as well as public policy.

Effective public health interventions depend upon a continuing and reliable source of information; resources should be allocated for the maintenance of the surveillance systems and for their regular evaluation. The data must be timely and representative of the population; they must be analysed and interpreted with feedback to the reporters and disseminated as widely as possible, including to those formulating and implementing public health policy. Allocation of resources devoted to surveillance for the purpose of informing prevention and control activities must be balanced with resources needed to implement those activities.

Life course epidemiology and analysis

Diana Kuh, Yoav Ben-Shlomo, Kate Tilling, and Rebecca Hardy

Introduction: what is life course epidemiology?

A life course approach in epidemiology investigates the biological, behavioural, and social pathways that link physical and social exposures and experiences during gestation, childhood, adolescence, and adult life, and across generations, to later life health and disease risk (Kuh and Ben-Shlomo 1997, 2004). Initially, the focus was on chronic diseases, particularly cardiometabolic and respiratory disease, where the life course perspective was used to integrate and extend three broad and apparently conflicting theories of disease aetiology: (1) fetal or developmental origins of adult disease (Barker 1998; Gluckman and Hanson 2006), (2) adult lifestyle (Krieger 2013), and (3) social causation theories (Marmot et al. 1984; Krieger 2013). Life course epidemiology then widened its gaze to a broader set of later life health outcomes that emphasized changes in function at the individual and physiological systems levels, through their period of development, maturation, and age-related decline. What had previously been seen as risk factors for subsequent later disease, were themselves seen as outcomes that required a fuller understanding of their natural history as well as life course determinants. The emphasis has been in exploiting the scientific value of the maturing birth cohort studies (Power et al. 2013) and other life course studies that have collected information on more than one phase of the life course. This has enabled researchers to test to what extent pre-adult factors influence later health, function, and disease risk, and whether the risk factor burden on these outcomes may be modified by early life risk and vice versa. In building its conceptual frameworks and models, life course epidemiology has built on relevant theories and concepts from scientists in other disciplines where a life course or developmental perspective was initiated earlier than it was for chronic disease epidemiology (Ben-Shlomo and Kuh 2002; Kuh et al. 2003). It has also discovered its roots in epidemiology and public health before the adult lifestyle model came to dominate chronic disease epidemiology in the second half of the twentieth century (Kuh and Davey Smith 1997). Now in the twenty-first century, a new interdisciplinary consensus is building, based on a life course approach to health and the changes in health with age in response to environmental challenges (Alwin 2012; Hertzman 2013; Kuh et al. 2014). By health, we mean how

people feel and function (at the individual, body systems, or cellular levels) and the disease risks they develop across life. In this chapter we describe these developments, update and elaborate our life course conceptual frameworks and models in response, and present examples that illustrate the application of life course methods that are a strength of life course epidemiology. We end by bringing up to date our reflections on the policy implications of taking a life course approach.

Background to life course epidemiology

A catalyst for the development of life course epidemiology was David Barker's imaginative studies that linked growth *in utero* or infancy to cardiometabolic and respiratory disease in later life (Barker 1998) which were interpreted as evidence for a critical developmental period with long-term consequences for chronic disease. Here, the life course approach encouraged three developments. The first was the replication and then systematic review of the growing epidemiological evidence that birthweight (a marker of fetal growth) or infant size was associated with adult blood pressure (Huxley et al. 2002), cardiovascular disease (Huxley et al. 2007), and diabetes (Whincup et al. 2008). This included investigating whether the associations between early life growth and adult disease were confounded by socioeconomic circumstances—generally they were not (Vagero and Leon 1994; Rich-Edwards et al. 1997; Hardy et al. 2003)—and what factors in adult life mediated or modified this early life risk; few adult cardiovascular risk factors were found to be mediators of the birthweight association with cardiovascular disease or mortality (Koupilova et al. 1999; Lawlor et al. 2004).

Second, life course epidemiologists also drew attention to potentially sensitive periods in childhood and adolescence, or during biological or social transitions in adult life, when the effects of physical and social exposures on long-term disease risk may be more marked than at other times. Here they drew on growing evidence from maturing birth cohort studies, as did Barker, so that the original fetal origins hypothesis widened to become more inclusive and was adapted to the developmental origins of adult disease (Gluckman and Hanson 2006). The emphasis was on fetal, childhood, and adolescent physical growth in relation to chronic

diseases and their adult risk factors (e.g. Cooper et al. 2001; Hardy et al. 2004; Barker et al. 2005).

Third, in respect of the adult lifestyle or social causation theories of chronic disease, life course epidemiology drew attention to the early acquisition of lifestyle and its cumulative effects (Schooling and Kuh 2002; Clennell et al. 2008; Cooper et al. 2011b), and to the impact of the socioeconomic environment in childhood as well as in adult life on later health and health inequalities (Davey Smith and Lynch 2004; Kuh et al. 2004). Here, there was extensive documentation of the impact of early socioeconomic position (SEP) on cardiovascular and respiratory disease, operating independently and/or cumulatively with the effects of adult SEP (Galobardes et al. 2004; Power and Kuh 2004; Singh-Manoux et al. 2004; Power et al. 2013). The extent to which social gradients in health and disease are explained by adult behavioural factors has long been a subject of investigation and debate; for example, a recent study has shown that better longitudinal characterization of health behaviours increased the power to explain the social gradients in mortality (Stringhini et al. 2010). But early life SEP acts as a cause of causes, through effects on the development and maintenance of health behaviours or through influencing adult social destinations (Phelan et al. 2004).

Other ways that early SEP was hypothesized to ‘get under the skin’ and affect adult health and health inequalities, was through socially patterned exposures and experiences leaving imprints (or being ‘biologically embedded’ (Hertzman and Boyce 2010)) in the structure and function of body systems during sensitive periods of development or biological transitions. Evidence for early life developmental risk explaining social gradients in health and disease was sought for—and in many cases found (Boyce et al. 2012). It may be that pathways associated with neurodevelopment are particularly pertinent in relation to early social adversity. In the related field of cognitive epidemiology (Deary 2012), there is growing evidence that childhood and adolescent cognitive ability is associated with adult mortality, morbidity, and better health. Whether these associations are explained by lifetime SEP, and whether both SEP and cognitive associations are driven by neurodevelopmental processes is of research interest.

From chronic disease to functional trajectories

The gaze of life course epidemiology has widened since the term was first coined in 1997, to include a whole range of other health outcomes—for example, studies have investigated the role of early life risk factors on the development of cancers (Potischman et al. 2004) and neuropsychiatric disorders (Factor-Litvak and Susser 2004) (where there was already a strong research tradition on childhood origins), and aspects of body function, such as musculoskeletal (Kuh et al. 2006a, 2006b), cognitive (Richards and Sacker 2003; Richards et al. 2004), and reproductive function (Kuh and Hardy 2002; Mishra et al. 2007; Rich-Edwards et al. 2010).

Studying biological function is a way of looking at health across the life before diseases are manifest, and estimating the impact of social and physical hazards that leave imprints on the function of body systems. These imprints reflect the ability of the organism to respond adaptively to ever changing environmental challenges,

and provide clues to aetiology. Functional trajectories provide a more dynamic concept than a simple dichotomous mortality or disease end-point categorization, incorporating the natural history and physiological trajectory of biological systems. Many functional measures are outcomes in their own right (e.g. lung, muscle, and cognitive function) as well as risk factors for later disease. Groups or classes of individuals who display different life course functional patterns can be considered and their lifetime determinants investigated (Silverwood et al. 2011; Mishra and Kuh 2012; Wills et al. 2012). Most functions display rapid growth and development in the early stages of life until a peak or plateau is reached at maturity, followed by a gradual decline with age (Fig. 5.20.1). These trajectories may reflect: (1) normal development and decline (trajectory A), (2) the influence of exposures or genetic factors that result in suboptimal development resulting in a reduced functional reserve at maturity (trajectory B), (3) the influence of exposures or genetic factors acting post maturity that result in accelerated age-related decline (trajectory C), and (4) a combination of trajectories B and C (trajectory D). There are also body functions that display different life course trajectories; for example, systolic blood pressure shows a rapid increase in adolescence, a gentle increase through early adulthood, a midlife acceleration beginning around the mid-30s, and a slowing and reversal of these increases into old age (Wills et al. 2011). However it is possible to reconceptualize the increase in midlife systolic blood pressure as reflecting age-related loss in arterial wall elasticity due to wear and tear from repeated pulsatile expansion and contraction (McEniery et al. 2010). The terminal decline in the oldest subjects remains more controversial and may reflect the composite effects of a healthy survivor effect, medication, heart failure, and failure of central neural control.

Life course epidemiology also has developed an interest in modelling physical and cognitive developmental trajectories that may provide clues to the imprinting of nutritional influences, infections, and other early life exposures either acting during critical or sensitive periods or accumulating over time. A natural extension of understanding functional trajectories is to try and explain biological ageing, the progressive generalized impairment of function

Fig. 5.20.1 Life course trajectories. A = normal development and decline; B = exposure during development reducing functional reserve at maturity; C = exposure acting post maturity accelerating age-related decline; D = combination of B and C.

Adapted from Kuh D, and Ben-Shlomo Y, *A Life Course Approach to Chronic Disease Epidemiology: Tracing the Origins of Ill-Health from Early to Adult Life*, Second Edition. Oxford: Oxford University Press, Oxford, UK, Copyright © 2004, by permission of Oxford University Press.

(‘senescence’) that occurs post maturity, and healthy biological ageing (Kuh et al. 2014), that is, the maintenance of optimal functioning for the longest period of time. The rate of functional decline reflects growing impaired physiological responses to environmental and behavioural challenges.

Environmental, behavioural, and physiological risk factors acting earlier in life may leave imprints on the development of peak function or the rate of decline, whereas these factors acting later in life can only affect the rate of decline or the ability to recover after an initial loss of function, for example, degree of heart failure after a myocardial infarction. A life course conceptual framework hypothesizes the relationships between biological, psychological, and social risk factors and health outcomes over time, taking into account their potential confounding, mediating, or interactive effects. A set of life course models hypothesizes how risk factors influence disease and functional outcomes (Kuh et al. 2003; Ben-Shlomo et al. 2013); Mishra and colleagues (Mishra et al. 2009) have developed a novel structured approach to distinguish critical, sensitive and accumulation models (see section on ‘Analytical challenges of life course epidemiology’). Now these life course frameworks and methods are being extended to investigate age at onset, duration and trajectories of these risk factors, and how they inter-relate in dynamic ways with functional trajectories of interest. They utilize a range of methodological approaches (see section on ‘Analytical challenges of life course epidemiology’) for modelling repeat continuous and binary outcome measures and link these to later outcomes or trajectories.

Historical and interdisciplinary perspectives

We have written extensively elsewhere to show that the idea that early life factors have long-term effects that stretch into adult life was the conventional wisdom in public health in the first half of the twentieth century (Kuh and Davey Smith 1993) and lay behind social welfare policies for mothers, babies, and young children that developed at this time (Dwork 1987). These early ideas in public health were influenced by biological and behavioural research into critical periods of animal and human development; and which influenced a new field of developmental science and the setting up of several US cohort studies of growth and development in the 1920s and 1930s (Kuh and Davey Smith 2004).

Epidemiological and public health interest in early life factors for adult health waned in the post-Second World War era as population cohort studies monitoring the development of coronary heart disease and cancers among middle-aged individuals became fashionable. However, pockets of interest remained: for example, in relation to the childhood origins of chronic bronchitis (Reid 1969; Colley et al. 1973), hypertensive and cardiovascular diseases (Abraham et al. 1971; Forsdahl 1977), and neuropsychiatric disorders (Stein et al. 1975). But it was the link that Barker postulated between nutritional experience *in utero* and adult chronic disease (Barker 1990, 1995), that really caught the scientific imagination and acted as a catalyst for further research, at a time of growing disenchantment with the adult lifestyle model of chronic disease. While initially built on evidence from ecological and historical cohort studies, investigations into the developmental origins of adult disease increasingly focus on potential

biological mechanisms; for example, studies of placental shape and function (Burton and Barker 2010) and epigenetics (Godfrey et al. 2011). In parallel, Boyce, Hertzman, and others are generating interest in a revitalized and interdisciplinary developmental science, ‘the developmental biology of social adversity’, which combines insights from disciplines such as neuroscience, genetics, and epigenetics, together with data from birth cohort and life course studies, to elucidate the biological pathways that link early experience to later health and health inequalities (Boyce et al. 2012; Hertzman 2013).

Scientists in life course epidemiology, and this new developmental science, acknowledge the relevant and influential research undertaken by Sir Michael Rutter and colleagues in the field of developmental psychopathology to understand continuities and discontinuities between childhood adversity and early disorders, and adult psychopathology (Rutter 1989, 2012b; Rutter et al. 2006). His work has revealed the great heterogeneity in how children respond to environmental adversity—when it may be good, tolerable, or harmful—and the need to understand resilience as a dynamic concept (Rutter 2012a).

More broadly, many disciplines champion a life course or a lifespan conceptual framework for organizing research on human development, maturation, and ageing and are increasingly identifying what they have in common, rather than their distinctive features. Life course sociology and lifespan psychology are examples (Mayer 2003; Alwin 2012). Life course sociology and life course epidemiology share an interest with demographers in understanding group differences through cohort effects that may reveal the impact of earlier life experiences on adult health and social outcomes (Myrskylä 2010).

Modern evolutionary approaches to science and medicine are highly relevant to all these disciplines. For example, Gluckman and colleagues have placed the developmental origins of adult disease within an evolutionary framework (Gluckman et al. 2009). They postulate how responses to environmental challenges can operate over different time scales: the role of homeostasis to restore equilibrium in the short term, the role of developmental plasticity in the early years to adapt to the environment and maximize the chance of reproductive success, and the force of natural selection over generations and millennia (Gluckman et al. 2009). Kirkwood and Austad (2000), Austad (2008), and others have provided evolutionary explanations for why we age, due to the decline in the force of natural selection in the post-reproductive phase of life which leaves the organism increasingly less able to repair the accumulating molecular and cellular damage. Here again heterogeneity and resilience, this time in older people, is of particular interest.

Life course conceptual models and their relationship to ageing

Our original life course models (Ben-Shlomo and Kuh 2002; Kuh et al. 2003; Kuh and Ben-Shlomo 2004) were developed to test the importance of timing and duration of exposures on later disease risk. They included: (1) a ‘critical or sensitive period model’ (mentioned earlier) when an exposure in earlier life has lifelong effects on structure or function that are either not modified or are modified by later experience and (2) the ‘accumulation of risk models’ (Fig. 5.20.2, models a and b) shown here where there is

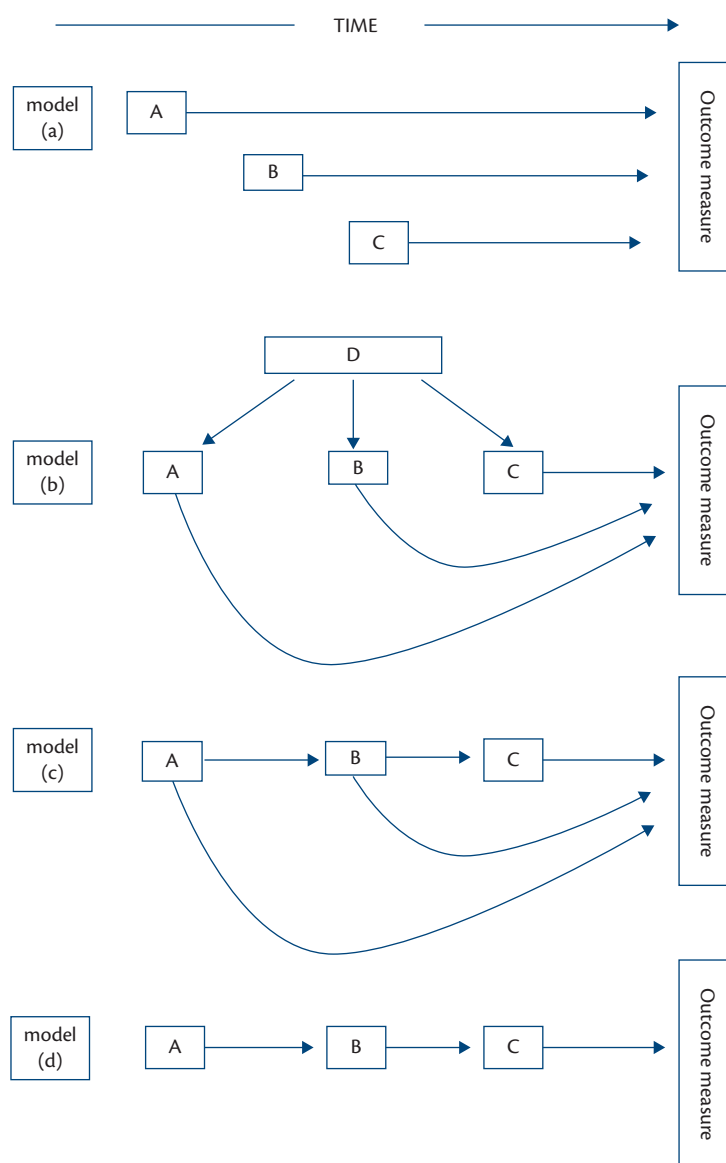

Fig. 5.20.2 Life course conceptual models.

Reproduced from Kuh D et al., *Journal of Epidemiology Community Health*, Life course epidemiology, Volume 57, Issue 10, pp. 778–83, Copyright © 2003, with permission from BMJ Publishing Group Ltd.

cumulative damage to biological systems over the life course or a ‘chain of risk model’ (Fig. 5.20.2, models c and d) where there is a sequence of linked exposures that lead to impaired function either through an accumulation of adverse effects across exposures or by the sequence leading to a ‘trigger’ exposure whilst the antecedent exposures are themselves of no direct consequence.

We have previously presented these as different classes of models though it is more sensible to view critical or sensitive period models as special subsets of an accumulation model (Ben-Shlomo et al. 2013)—hence the effects of exposures over different time periods do not add up in a simple additive fashion but differ in the strength of effect in a quantitative sense (sensitive period) or in a qualitative sense so that they can only be observed in one time period (critical period). For example, duration of obesity may increase risk of breast cancer in women in a simple linear dose–response relationship (accumulation). If, however, being

obese during puberty further increased cancer risk independent of duration, this would suggest that puberty is a sensitive period of exposure for future carcinogenic risk. Finally, if one only observed an increased risk with obesity in puberty and being obese outside this period was not related to cancer risk then there would be evidence for a critical period effect. In this case women who were obese in puberty but remained obese outside this time window would have the same risk as those who were only obese during puberty—hence there would be no evidence in support of accumulation of effect.

These life course models do not accurately represent the complexities of life course epidemiology as practised today when researchers are interested in the dynamic interplay of developmental, risk factor (behavioural or environmental), and ageing-related trajectories. The challenge is to model the characteristics of risk factors over time (age at onset, duration, and change with age)

with changes in the functional outcomes of interest. While there is now considerable experience in modelling risk factor trajectories, such as physical growth, there is much more limited experience in investigating how functional outcomes change with age, and the lifetime determinants that drive this change, in addition to those that establish the initial level (Wills et al. 2012; Lawlor and Hardy 2014).

Furthermore, given that there is great heterogeneity in biological ageing, our models need to be able to take into account this variation in resilience to environmental challenges with age. We identify two sources of resilience to ageing post maturity. The first is intrinsic ‘compensatory reserve’; this may reflect structural factors, for example, size of heart muscle, functional capacity, that is, the efficiency of the heart to generate cardiac output or recuperative function, in other words, the ability of body systems to compensate physiologically or repair damage with varying degrees of success when faced with acute or chronic low-level challenges. We envisage compensatory reserve as an intrinsic biological phenomenon which preserves function but deteriorates with age, probably in a non-linear fashion and possibly in parallel across multiple domains (e.g. vascular, neurological, immune, homeostatic systems) in those who will become frail. For example, the degree of heart failure subsequent to a heart attack will not only depend on the location of the infarction but also on the premorbid structure and function and the ability to open up collateral circulation in

the immediate postinfarction period thereby salvaging cardiac muscle and function.

The second aspect of resilience in ageing is the individual’s extrinsic responses or adaptations when faced with age-related declines, by altering behaviour or the environment to modify the effect on, or slow the rate of, functional decline. So, for example, the ‘use it or lose it’ hypothesis argues that continued cognitive stimulation will maintain synaptic connectivity despite neurodegenerative changes and hence slow down decline or maintain cognitive function due to enhanced cognitive reserve (Stern 2002).

Ferrucci and Studenski (2012) identified four key ageing phenotypes where growing disequilibrium or dysfunction in response to environmental challenges can lead to frailty, and where conversely, maintenance would represent healthy biological ageing: (1) central nervous system (CNS) integrity or neurodegeneration, (2) homeostatic regulation or age-related dysregulation in signalling pathways that maintain homeostasis (encompassing both the endocrine and immunological systems), and the extent of age-related changes in (3) body composition (muscle, fat, and bone), and (4) in energy capacity and consumption.

An integrated life course model of ageing is illustrated in Fig. 5.20.3. From a life course perspective we are particularly interested in how growth and development (box 1 in Fig. 5.20.3) impact these four phenotypes (box 2), related physiological systems such

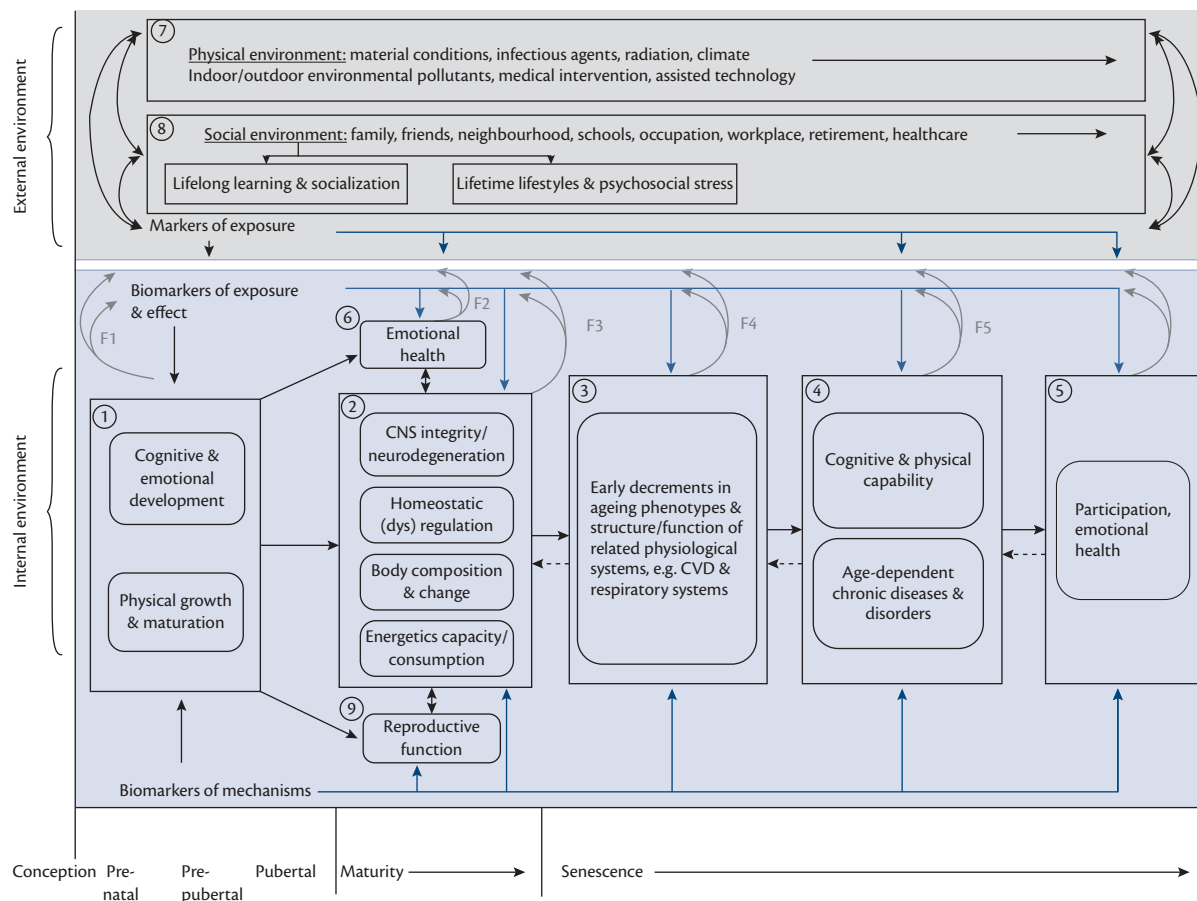

Fig. 5.20.3 Integrated life course model of ageing.

as the cardiovascular and respiratory systems (box 3), and the phenotypic emergence of their consequences for physical and cognitive capability (the capacity to undertake the physical and mental tasks of daily living) (box 4). Being able to detect early markers of an accelerated trajectory of decline, and before it is manifest in adverse changes to physical and cognitive capability, is one of the cornerstones of the life course perspective on ageing because it offers an opportunity to delay the onset of decline or its rate of change through preventive strategies.

Our life course model of ageing also encompasses the emotional health of older people and their continued participation in society as a health phenotype in its own right (box 5) which may be threatened by functional decline. But emotional health is intertwined with physiological ageing, as both a determinant and a consequence (box 6). Early emotional development predicts adult emotional health and life chances, and lifetime emotional health influences physiological ageing as well as determines individual capacity for psychological and social adaptation. The feedback loops in the diagram (labelled F1–5) illustrate the possibility of physiological compensation, or psychological and social adaptation through modifying behaviour or the surrounding environment.

In our model, we have separated out lifetime physical and social environments (boxes 7 and 8) but show strong links between the two. The social environment is shown to influence the ageing trajectory not only through exposures to material conditions and other aspects of the physical environment, but also through life-long learning and socialization, lifetime lifestyles, and exposure to psychosocial stressors. An important element of the life course approach is that it captures environmental characteristics before impairments emerge so that the unfolding interaction between individuals and their environments can be better understood.

This model also considers reproductive function (box 9), thus integrating our life course model of ageing with the broader evolutionary framework. The adaptations made during developmental plasticity to promote the subsequent reproductive capacity of the organism may have later deleterious effects (the ‘live fast, die young’ hypothesis). A woman’s physiological response to the challenge of pregnancy and childbirth provides clues to adaptive capacity and reproductive characteristics (such as hypertension in pregnancy, offspring low birthweight, and early menopause) which may act as sentinels for later disease and accelerated ageing (Rich-Edwards et al. 2010).

This integrated life course model of ageing assumes an intimate connection between brain and body ageing, and between physical and cognitive capability. A common causal account of ageing may operate at various levels, from brain circuitry to cellular energetics but we still need to empirically test these assumptions. A recent systematic review (Clouston et al. 2013) of studies that have investigated the dynamic relationship between physical and cognitive function in longitudinal ageing cohorts found some evidence of associations but the findings were not sufficiently strong or consistent to support a common cause explanation. Comparability between studies was hindered because of differences in the measurement and operationalization of the underlying constructs.

The stochastic nature of ageing—the nature of chance—means that this integrated life course model is unlikely to predict individual outcomes, but it may explain group differences in ageing. It

provides insight into the lifetime characteristics of individuals and their environments that drive ageing, and that could be targeted to extend healthy active lives. The development of more refined markers or biomarkers of exposure and effect, and biomarkers of underlying mechanisms would facilitate such investigations. For example, we simplify repeated measures by aggregating them into a mean summary measure. But the variability of measures may also add information. So, Rothwell et al. (2010) have demonstrated that not just mean blood pressure but blood pressure variability for a given mean level independently increases risk of cardiovascular disease. It is unclear whether greater variability reflects additional structural changes (e.g. arterial stiffness) which are harmful or is a marker of failing homeostatic mechanisms that maintain blood pressure within a limited range. Similar observations have been seen for gait speed in the elderly whereby a larger standard deviation of gait speed rather than mean level predicts future falls risk and probably reflects underlying neurological dysfunction as this is also seen with disorders such as Parkinson’s disease (Frenkel-Toledo et al. 2005).

Study designs for life course epidemiology

Any epidemiological design can in theory be used for life course studies as long as exposures in an earlier period can be related to future outcomes. The rise in life course epidemiology followed on directly from both ecological studies and the ingenious identification of historical birth records which enable the construction of a historical cohort study (Barker et al. 1989). Ecological designs as well as time trend analyses remain a popular approach to test the relative importance of early versus later life exposures such as SEP (Ben-Shlomo and Davey Smith 1991; Bengtsson and Lindstrom 2000; Myrskylä 2010). Epidemiologists are often attracted to historical cohort studies as outcomes can be quickly related to past exposures and hence are relatively cheap to undertake. In addition, survivors from the initial cohort can then be invited for further data collection and hence the study can be converted into a prospective study with the addition of new phenotypes (Syddall et al. 2005). The obvious disadvantages are that data have usually been collected for non-research purposes (though this is not always true as in the Boyd-Orr cohort (Martin et al. 2005) which was originally a cross-sectional study), and generally only have data at one time point with data on important confounders usually missing. In addition, end points tend to be limited to mortality or possibly morbidity if ethical permission is provided to link data to hospital admission or primary care records. This approach has been used not just for birth records but also for childhood growth records. The Copenhagen Cohort Study on Infant Nutrition and Growth linked data from 117,415 Danish women when they were aged between 8 to 14 years to the cancer registry so that 3340 cases of breast cancer could be identified (Ahlgren et al. 2004). They found that high birthweight, tall stature at 14 years, and peak growth at an early age were independent risk factors for breast cancer. This was further supported by another school-based follow-up which found that early peak height velocity, a proxy marker for puberty, was also associated with higher insulin-like growth factor 1 (IGF-1) (Sandhu et al. 2006a). The latter is known to be anti-apoptotic and has been associated with increased risk of premenopausal breast cancer (Renehan et al. 2004).

The conventional prospective cohort study is usually more suited for life course epidemiology, but traditionally studies of chronic disease would only recruit adults in midlife hence the availability and maturation of the UK birth cohorts have provided ideal datasets to test many life course hypotheses. Birth cohorts are costly but they provide a very rich dataset that can test a wide range of hypotheses and the integration of genetic and epigenetic data makes them extremely valuable resources.

Another approach has been the use of natural experiments and the long-term follow-up, usually unplanned at the time of design, of past randomized trials. The best known example of the former has been the series of studies on the survivors of the Dutch famine. The timing of the famine imposed by the German troops on the inhabitants of Amsterdam enabled researchers to test whether the timing (early, mid, late gestation) of severe nutritional deprivation during pregnancy had an effect on early childhood development (Stein et al. 1975), and more recently cardiovascular, metabolic disease (Ravelli et al. 1998), and a range of traits including epigenetic methylation patterns (Heijmans et al. 2008). Follow-up of conventional randomized controlled trials has also been undertaken but here only a single hypothesis related to the specific intervention can be tested, though the problem of confounding may be overcome assuming no systematic loss to follow-up by randomization status. For example, Singhal and colleagues followed-up premature babies who were randomized to either breast versus formula feeding or high- versus low-nutrient feeds (Singhal et al. 2001). In these studies the response rate at follow-up was low (around 20 per cent) though there do not appear to be major differences at baseline between those who re-attended compared to those who did not at baseline. From these data they suggested more rapid growth in the immediate postnatal period may be deleterious in terms of adolescent risk factors ('growth acceleration hypothesis') (Singhal et al. 2004). In contrast, a village-based stepped wedge cluster trial in Hyderabad, India, found that children who received nutritional supplementation were taller at follow-up, indicating some effect on development and had better insulin function as well as less stiff arteries, though the differences were modest (Kinra et al. 2008).

Family-based designs have traditionally been used by psychologists in their efforts to explain how much of a trait such as intelligence, can be explained by genetic or the shared and non-shared environment (Plomin and Daniels 2011). Within the context of life course epidemiology, they have regained interest as a method to disentangle causal from confounded associations. Comparing relationships within and between family members—between generations or siblings or twins, for example—can help to clarify the mechanisms underlying associations in life course studies and help to determine causality (Lawlor and Mishra 2009). Prenatal influences can be studied by comparing the relationship between the exposure experienced by the mother during pregnancy and outcome in the offspring with that between the experience of the father to the same exposure and offspring outcome (Davey Smith et al. 2009a). In the Avon Longitudinal Study of Parents and Children (ALSPAC), the effect of maternal smoking on childhood obesity was of a similar magnitude to the effect of paternal smoking (Leary et al. 2006) suggesting that maternal smoking does not have a direct intrauterine effect on childhood obesity, but rather that any association may be due to the confounding effects of lifestyle in parents who smoke unlike birthweight which was

much more strongly associated with maternal smoking. The use of maternal versus paternal comparisons with offspring outcomes has been further extended with the use of genetic information as instrumental variables. Lawlor and colleagues (Lawlor et al. 2008) tested the developmental overnutrition hypothesis which argues that the increase in childhood adiposity reflects the cumulative inter-generational effect of obese mothers having more obese children who in turn become obese mothers. This study not only used maternal and paternal body mass index but also the maternal FTO genotype which is associated with body mass index but not associated with the usual socioeconomic confounders (see discussion of Mendelian randomization in 'Analytical challenges of life course epidemiology'). They found stronger maternal than paternal associations, even after accounting for a 10 per cent non-paternity rate, but there was no FTO offspring obesity association conditional on offspring FTO status. The use of genetic and environmental interactions or epigenetic effects on fetal development is likely to further expand opportunities for hypothesis testing. Many past studies have failed to find an association between maternal alcohol drinking during pregnancy and offspring IQ but mothers who drink more tend to have higher SEP which would mask any association. Lewis and colleagues in the ALSPAC cohort were able to show that a risk allele score using four alcohol metabolizing genes was associated with worse cognition but only if the mother reported moderate drinking (1–6 units per week) whilst there was no effect of the genetic score amongst abstainers (Lewis et al. 2012).

Life course epidemiologists have formed research collaborations that involve a number of cohort studies, such as HALCYon (Healthy Ageing across the Life Course, <http://www.halcyon.ac.uk>) (Kuh et al. 2012), and FALCon (Function Across the Life Course) to increase the sample size and power to investigate lifetime risk factors on longitudinal phenotypes, and to test whether findings are replicated across cohorts in a systematic way. The collaborations have developed experience in data harmonization to derive comparable phenotypes across the cohorts, and in cross cohort methods (Cooper et al. 2011a; Wills et al. 2011; Hardy et al. 2013).

Cross-cohort comparisons also enable one to examine for generalizability or unique birth cohort effects and can help disentangle causal from confounded associations as confounding structures may vary in different populations. A two-cohort comparison was undertaken between the UK-based ALSPAC cohort and the Brazilian Pelotas cohort as in the former higher SEP was associated with greater breastfeeding whilst in Pelotas there was no socioeconomic association (Brion et al. 2011). Not surprisingly, the ALSPAC study demonstrated an association between breastfeeding and lower blood pressure, lower body mass index (BMI) and higher cognition even after adjustment for a wide range of confounders. In contrast there was no association between breastfeeding and blood pressure or BMI in Pelotas but the association with cognition remained and is supported by findings from the PROBIT randomized trial of breastfeeding (Kramer et al. 2008). Thus it can be concluded that associations of breastfeeding with child blood pressure and BMI are likely to reflect residual confounding, while breastfeeding may have causal effects on cognitive function. In this example both cohorts had subjects of a similar age but it is more common to have cohorts with subjects of very different ages. In this scenario, one can still use the comparisons

to triangulate across clinical and subclinical end points. For example, we could test whether breastfeeding is protective for cardiovascular disease by seeing if in the oldest cohorts (ages greater than 60 years) breastfeeding is associated with cardiovascular mortality and morbidity whilst younger cohorts (ages less than 60) could examine for preclinical surrogates such as carotid intimal medial thickness or echocardiographic changes to the heart. The consistency of findings across the life course both supports a causal explanation (as the confounding structure may differ by secular period) as well as providing insights into the onset of the pathophysiological process.

Analytical challenges of life course epidemiology

The statistical analysis of life course data is complex and challenging as it aims to study how risk factors from across the whole of life jointly influence later health and increasingly how life course risk factors influence patterns of functional change across the life course (see section entitled 'From chronic disease to functional trajectories'). Whatever statistical model is used, analyses attempting to disentangle the life course effects still require understanding of the underlying biology, and careful consideration of confounding, intermediate variables, and potential biases.

Exposures which are measured repeatedly over time (e.g. when relating infant weight gain to later outcomes) present three related analytical problems: (1) repeated measures on the same individual are likely to be correlated, (2) the potential high dimensionality of the resulting exposure (e.g. six repeated measures of weight over the first year of life (Tilling et al. 2011a)), (3) specifying the hypothesis to be tested (e.g. is average weight gain related to the later outcome? Maximum weight gain? Total weight gained?). One way of dealing with the first two problems is to derive simple summary measures such as an area under a growth curve (Li et al. 2004), the length of time an individual has been overweight (Wills et al. 2010; Silverwood et al. 2013), or the number of time points an individual has been in a disadvantaged SEP (Davey Smith et al. 1997; Wamala et al. 2001). However, this approach assumes an underlying model, does not test alternatives and does not address the impact of timing of an exposure. For example, age at onset of obesity was associated with blood pressure at 53 years, but whether duration of obesity or BMI at 53 years was the main driver of this association could not be teased out (Wills et al. 2010).

In order to distinguish a critical period, or more likely a sensitive period, model from an accumulation model, Mishra et al. (2009) operationalized these models algebraically. First, a saturated model is fitted, in which each of the possible life course trajectories is allowed to influence the outcome in a different way. Each alternative life course model is then tested against this saturated model, using a *p*-value-based approach to choose the best-fitting model. This approach was developed in the context of repeated measures of a binary classification of occupational social class (e.g. high versus low SEP). The ability to distinguish between the various models is limited by the variability in trajectories within any dataset, and the timing and spacing of the measurement points. In the original paper, measures that spanned three relatively equal-spaced time periods were used, whereas in an application with only childhood and adult SEP, the adult SEP exposure

covered a much longer time period than the childhood measure (Birnie et al. 2011).

When considering a continuous repeated exposure (such as body size), several methods for relating change to later outcomes have been proposed. Simple methods, including *z*-score plots showing standardized growth measures over time in different outcome groups, and methods based on multivariable regression have been widely used to address early growth and health. Life course plots were developed to visualize both size and growth, and consist of plotting the regression coefficients from a model relating the outcome to all body size measures simultaneously against their respective measurement ages and joining the points (Cole 2007). To address the issue of uninformative ages and collinearity between measures, ages where the measure appears unrelated to the outcome may be removed and the model refitted and a new plot produced. Cole provides an example where weight at ages 4 and 6 are uninformative in relation to subsequent age at menarche (Cole 2007), and the final life course plot includes positive coefficients for weight at birth and 2 years and a negative coefficient for weight at 7 years. The interpretation is thus suggestive of two separate processes: one acting early in life where above-average weight delays puberty and the second in later childhood where a slow rate of weight gain relative to peers is related to later puberty. This practice of adjusting for a later measure of body size when interpreting the association between an earlier measure of body size and outcome has been the subject of much debate. If birthweight has a positive association with later body size, which is itself positively related to the outcome, then the association between birthweight and outcome can change from positive to negative on conditioning on the later body size variable (termed the 'reversal paradox' (Tu et al. 2005)). To avoid this problem, conditional change measures have been proposed, whereby residuals from models of each body size measure regressed on previous body size measures are derived (Adair et al. 2009). By definition, these residuals are all independent of each other and can be included in the same regression model. It is then possible to test whether change in one period has a stronger association with the outcome than change in other periods (Wills et al. 2010). Alternatively, path analysis can be used to model simultaneously the direct and indirect effects of an early body size measure on an outcome (Gamborg et al. 2009). The saturated path model is a combination of the conditional change model parameterization and the size model parameterization (Wills and Tilling 2014). As well as the need for careful interpretation, a major disadvantage of all these methods is that measurements must be taken on all study members at the same age and that individuals are dropped from analysis if they have missing measurements (unless multiple imputation (e.g. De Stavola et al. 2004) or other procedures are carried out).

To overcome the need for balanced data, and to shed light on the relative importance of exposure at different times, estimates of change from growth curves (using multilevel or mixed-effects models) have been used to summarize repeated exposures. Growth curves may be smooth (e.g. using natural or cubic splines (Silverwood et al. 2009), fractional polynomials (Wen et al. 2012), or extended splines (Pan and Goldstein 1998)) or connected periods of approximately linear growth (e.g. using linear splines (Tilling et al. 2011a)). Linear spline random effects models have been fitted to repeated measurements of weight between birth and 5 years of age in the Barry Caerphilly Growth Study (Ben-Shlomo

et al. 2008). A model was fitted with two knots (selected in this case to be at 5 months, and 1 year and 9 months) allowing different gradients in the three time periods. The between-subject random effects (i.e. birthweight and each of the three slopes defined as immediate postnatal, infant, and child weight velocities) were then related to blood pressure in young adulthood and suggested that low birthweight and rapid postnatal growth were associated with higher systolic blood pressure, but that only immediate postnatal weight gain was associated with higher diastolic blood pressure. The periods into which time is partitioned may be driven by model fit (e.g. by choosing the combinations of knots), from a specified set, which provide the best fit as assessed by measures such as the AIC (Akaike information criterion) or BIC (Bayesian information criterion) or, a priori, based on biological changes in growth patterns. Aspects of the growth curve other than estimates of change can be derived, such as the location of the BMI peak between 5 and 13 years (Silverwood et al. 2009). A study examining growth between 9 and 18 years and with up to 65 repeat measurements derived maximal velocity and age at peak height velocity, which was used as a surrogate for the timing of puberty (Sandhu et al. 2006b) showing that younger age at peak height velocity was associated with higher adult IGF-1 levels. A more recent analysis of the same anthropometric data using the SuperImposition by Translation And Rotation (SITAR) model (Cole et al. 2010) identified three random effects for each individual which summarized their growth patterns; these represent size, growth tempo, and growth velocity. This model was able to explain 99 per cent of the variance in growth patterns and then each parameter was related to adult levels of IGF-1. Many of these models can also be fitted as joint models using structural equation models (De Stavola et al. 2006) or multivariate multilevel models (Goldstein and Kounali 2009; Macdonald-Wallis et al. 2012).

As an alternative to relating derived aspects of a growth trajectory to an outcome, individuals can be classified into groups of people with similar trajectories (using latent class analysis (Nagin and Tremblay 2001; Nagin and Odgers 2010) or growth mixture modelling), and class membership related to the outcome. Latent class analysis was used to summarize childhood overweight patterns in relation to kidney function (Silverwood et al. 2013) and wheezing phenotypes in the first 6 years of life in relation to atopy and lung function in later childhood (Henderson et al. 2008). One study, however, suggested that the latent trajectory classes (extracted using growth mixture models) of midlife change in blood pressure contained the same information as the intercept and slope from a random effects models, when predicting angina (Wills et al. 2012). The latent classes derived may not always coincide with hypotheses of interest, and there must be a priori reasons for thinking that distinct subpopulations (or classes) exist (Tilling et al. 2011b).

In situations when we are interested in two body size measurements, there is a third variable of interest (the difference or growth) that is a linear function of the other two and this has been termed the *duality of size and growth* (Cole 2007; Wills and Tilling 2014). This duality means it is impossible to estimate mutually distinct effects for all three parameters and is analogous to the problem of disentangling age, period and cohort effects. Partial least squares (PLS) regression has been used to attempt to overcome this problem by extracting functions of the exposures which explain the highest percentage of variance in the outcome (Tu et al. 2010;

Heys et al. 2013). This method was used to relate blood pressure at 11 years to height and weight during childhood, and showed that systolic blood pressure was related to size at birth, 3 months and 11 years, as well as change in BMI between 3 months and 11 years (Heys et al. 2013).

To be of policy relevance the causal nature of observed associations needs to be established. Directed acyclic graphs (Greenland et al. 1999; Greenland and Brumback 2002) can be used to articulate assumptions made about potential confounding and mediating variables, and to help identify variables to be controlled for in analyses (Hernan et al. 2002). Path analysis or structural equation models can be used to parameterize the causal graph (Greenland and Brumback 2002). Given the time frame over which associations operate in life course epidemiology, the potential for confounding by multiple variables across the life course is great. Methods available to adjust for the bias due to confounding in observational studies include: adjustment for confounders in regression models, stratification by confounders, use of propensity score (Rosenbaum and Rubin 1983) (or other matching) methods to mimic randomized trials by creating subgroups of individuals with similar likelihood of having the exposure, and instrumental variable methods (Greenland 2000). Because an instrumental variable is related to the outcome only through the exposure, and is unrelated to any confounders of exposure and outcome, the relationships between instrument and outcome and between instrument and exposure can be used to derive an unconfounded estimate of the causal effect of exposure on outcome. Examples of instrumental variables in epidemiology include offspring BMI as an indicator of own BMI in analysis relating BMI and mortality to avoid reverse causation (Davey Smith et al. 2009b) and age-specific retirement incentives as an instrument to relate retirement to later health (Behncke 2012). A more common use is of genetic instrumental variables in Mendelian randomization (Davey Smith and Ebrahim 2004; Didelez and Sheehan 2007). For example, although greater adiposity was associated with increased odds of psychological distress, Mendelian randomization analysis using genetic variants robustly associated with adiposity suggested an inverse association (Lawlor et al. 2011). In contrast, Mendelian randomization analysis suggested a causal link between childhood BMI and age at menarche (Mumby et al. 2011). A two-step epigenetic Mendelian randomization method has now been proposed as an extension which may help establish the causal role of epigenetic processes in pathways to disease (Relton and Davey Smith 2012).

An added complication, called time-dependent confounding, occurs in life course analyses when confounders are themselves measured repeatedly over time, and early exposures influence these later confounders (Daniel et al. 2012). Standard statistical models may be biased when there is time-dependent confounding, and this bias may not be removed by adjusting for either the baseline value of the covariate, or the time-updated covariate (Daniel et al. 2012). Methods such as marginal structural models, g-estimation, or the g-computation formula may be used to estimate the effect of an exposure on an outcome in the presence of time-dependent confounding (Robins 1986; Robins et al. 1992, 2000; Daniel et al. 2012).

In all the methods described, long-running population-based studies inevitably result in missing data and measurement error which may bias findings. Methods for dealing with missing data are well developed, although implementation can be complex in a

life course setting. Multilevel models (estimated using maximum likelihood) allow for missing data, provided that the data are missing at random (Steele 2008), and thus have an advantage over regression-based methods (Peters et al. 2012). In ageing research, because of the high mortality rates and the increased likelihood of missing data being non-ignorable, the potential bias induced must be considered (Enders 2011).

Public health implications

There is a growing interest in the policy implications of the accumulating evidence from life approaches in epidemiology and other disciplines that factors across life shape adult health and health differentials (Butland 2007; Barondess 2008a, 2008b; Foresight Mental Capital and Wellbeing Project 2008; Shonkoff et al. 2009; Marmot 2010; Scientific Advisory Committee 2011; Halfon 2012; Shonkoff et al. 2012). Currently, there seems to be more emphasis in the United States on calling for early life interventions, and somewhat more emphasis in the United Kingdom on interventions across life.

In looking for some broad principles on which to base a life course approach, we would suggest that a risk-based model of medicine that starts in midlife is too late. Clearly from a life course perspective we should aim to maximize the level of peak function achieved by maturity as well as modifying the age at onset and rate of functional decline. The primary prevention of risk factors is a priority, coupled with 'earlier, more vigorous and longitudinally maintained management of risk factors' linked to greater integrated care, both vertically and horizontally (Barondess 2008b). This means that in offering individuals help to manage their health, service providers need to take account of prior life and health experiences as well as complex preventive or care needs that cut across clinical specialities, or across health and social domains. Life course interventions to promote adult health and reduce health inequalities need to enable the best early nurturing environments as well as recognizing opportunities to take advantage of later life modifiability, plasticity, and resilience, especially during later biological and social transitions (e.g. during adolescence, pregnancy, becoming a parent, and during the menopausal and retirement transitions).

At the population level, many of the policy implications would appeal to a broad constituency: removing unnecessary physical and social environmental hazards (such as contaminated food) and creating health-promoting neighbourhoods in which individuals live and work must remain priorities. The message from a life course perspective is that these types of improvements to the environment are likely to have long-term as well as short-term health benefits; this can be a difficult message where political interests are often focused on short-term gains. The evidence for these long-term effects will continue to come from observational studies, increasingly using study designs that are more able to confer causal inference, as setting up randomized control trials to study such long-term effects is not practical nor, in many cases, ethical.

Reports that take a life course perspective in recommendations to reduce health inequalities are clearly relevant to this debate. For example, the Marmot Review has six policy objectives for reducing health inequalities: giving every child the best start in life; enabling all children, young people, and adults to maximize their

capabilities and have control over their lives; create fair employment and good work for all; ensure a healthy standard of living for all; create and develop healthy and sustainable places and communities; and strengthen the role and impact of ill-health prevention (Marmot 2010). Other UK reports, for example, on mental capital and well-being (Foresight Mental Capital and Wellbeing Project 2008), obesity (Butland 2007; Department of Health 2011), and reproductive health (Scientific Advisory Committee 2011), also champion a life course perspective.

In adulthood, there are risk factors that are common to many later life health outcomes, which have themselves been shaped by exposures and experiences from early life onward. For example, a recent assessment of the risk factors for dementia and cognitive decline (Anonymous 2010) showed the best evidence for midlife obesity, high blood pressure and elevated cholesterol, and smoking. The strongest evidence for modifiable factors that protected against dementia or cognitive decline was for physical activity and moderate alcohol intake; there was also some evidence that following a Mediterranean diet and being socially active were protective. These risk and protective factors are clearly relevant for many other ageing outcomes (Kuh et al. 2014).

The principles and objectives of a life course approach to improve lifelong health and reduce health inequalities may be fairly straightforward to postulate. But designing, implementing, and evaluating effective interventions that operate at one or more key life stages is clearly challenging, as is creating the political will to fund interventions and to implement those that are successful across the wider society, especially during economic recessions (McKee et al. 2012). There is a danger of interventions generating further inequalities; this is more likely in individual-based rather than structural-based interventions (White et al. 2009). Effective interventions require input from those with skills in translation or implementation in population sciences and public health (Ogilvie et al. 2009; Lobb and Colditz 2013), working with researchers and policy and practice stakeholders, and using all types of evidence, from basic science and epidemiology to evaluation, to build a strong evidence base.

Public health in the twenty-first century needs a dynamic and life course concept of health that reflects the 'ability to adapt and self-manage' (Huber et al. 2011) based on resilience to cope and maintain and restore one's integrity, equilibrium, and sense of well-being. The next phase of the life course epidemiology research agenda will be to measure and characterize compensation and adaptation effectively, and investigate how they change over time, their consequences, and life course determinants. Life course epidemiologists need to respond to this challenge, and to the challenge of translating these findings into effective interventions and public health policy.

Sociology and psychology in public health

Stella R. Quah

Introduction to sociology and psychology in public health

The disciplines of sociology and psychology have common links both conceptually and methodologically but they also differ in interesting ways. They differ in overall scope: psychology typically focuses on the individual while sociology examines the individual's social action (agency) and the community's social and physical context (structure) within which they live, interact, work, and play. One important similarity between sociology and psychology is that both disciplines have a dedicated subfield for the study of health and illness. These subfields are, respectively, medical sociology and health psychology. Thus, in line with the objective of this volume, the focus of this chapter is on the contributions to public health by medical sociology and health psychology, the two subfields most relevant to public health.

One plain but important notion about illness runs across the three fields of knowledge, medical sociology, health psychology, and public health. That notion is that infectious disease may begin with one individual but, if left unchecked, it can affect entire continents. This principle was highlighted by a British physician, Southwood Smith, in the nineteenth century. Smith (1866) was alerting the health authorities on the need to investigate and control infectious diseases. By the twenty-first century, sociology and psychology have accumulated a wealth of research on the impact of individual and collective social behaviour on health to show that Southwood Smith's notion applies also to people's behaviour and social conditions associated with non-infectious diseases and, indeed, to health-related phenomena as a whole.

The discussion that follows is presented in four sections: sociology and public health, psychology and public health, the contribution of both disciplines to public health training, and conclusion. The sections on sociology and psychology cover the same three themes: the highlights of their respective theoretical contributions, the main methodological approaches that are relevant to public health, and a succinct summary of areas of research that illustrate the contributions of medical sociology and health psychology to the field of public health. The list of references documents the arguments made in the text and serves as further reading on the historical as well as most current information on what medical sociology and health psychology offer to public health researchers and practitioners.

Sociology in public health

The sociological analysis of health and illness can be traced back to the beginnings of sociology as an area of systematic knowledge in the late 1800s. Sociology's pioneers in Europe investigated the influence of cultural, socioeconomic, and political conditions in the community on individuals' social action. Two of the pioneers were Emile Durkheim (1858–1917) in France and Max Weber (1864–1920) in Germany. In the midst of the development of sociological theorizing, while sociology pioneers were examining the nature and dynamics of society and social action, the spread of infectious diseases was exerting a heavy toll in Europe. The damage caused by epidemics alerted some British and European medical authorities to the possible connection of three phenomena hitherto seen as unrelated by medical experts: social conditions in the community, social behaviour, and public health. Among the first physicians to presume that connection existed were Virchow and Billings. A notable German pathologist, Rudolf Virchow (1812–1902), seen as 'a dominant figure in German medicine' (Shryock 1974, p. 202) was perhaps the first medical scientist who considered medicine as a social science (Elling and Sokołska 1978, p. 14). John Shaw Billings, an American surgeon and the first publisher of the *Index Medicus*, wrote on the link between 'hygiene and sociology' around 1879 (Shryock 1974, pp. 182–183; Cockerham, 2010b, p. 2). In a 1894 article on the social factors of illness another physician, Charles McIntyre, used for the first time the term 'medical sociology' (Cockerham 2010b, p. 2).

The initial phase of medical sociology was rooted in research by sociologists working in medical academic settings and in public health or biomedical clinical settings (Elling and Sokołska 1978). Medical sociology research and publications paved the way to the inclusion of medical sociology courses in the medical curriculum at American and British universities after the Second World War (Elling and Sokołska 1978; Cockerham 2010, pp. 2–3), as I explain later. Some of the signposts of the formalization of medical sociology as a subdiscipline of sociology are the establishment of the Medical Sociology Section of the American Sociological Association in 1959, the Research Committee on Medical Sociology of the International Sociological Association in 1963,¹ and the Medical Sociology Research Network in the British Sociological Association in 1969 (Reid 1976).

Research publications in medical sociology include journal articles and books. Among the most important domain-specific

international refereed journals are the *Journal of Health and Social Behaviour (JHSB)*, the dedicated medical sociology journal of the American Sociological Association; *Social Science & Medicine (SSM)*; *Sociology of Health and Illness*; and *Health Sociology Review*, the journal of the Health Sociology Section of the Australian Sociological Association. There are several textbooks in medical sociology; one of the most established is Cockerham's (2010b), already in its 11th edition. Among serial books is the *New Blackwell Companion to Medical Sociology* (with editions published in 2001, 2005, and 2010) and the *Handbook of Medical Sociology (HMS)*. The first edition of the HMS was published in 1963 (Freeman et al. 1963) and it discussed 'the potential of the sociological enterprise for understanding the etiology, diagnosis, and treatment of diseases; the ways health care is provided and funded; the societal and communal commitment to the support of health activities; and, indeed, the very definitions of health and illness'. Looking back at the first three editions of 1963, 1972, and 1979, the editors of the fourth edition wrote that, 'the promise of medical sociology [is now] replaced by hard evidence as to its utility' (Freeman and Levine 1989, p. 1). These authors correctly pointed out that medical sociology uses the full range of sociological theories and methodologies (1989, p. 7).

In concert with the increase in research and publications by the 1980s, medical sociologists were also 'actively involved in public health programs, and . . . accredited schools of public health in the United States were required to provide formal training in the social and behavioral sciences' (Coreil 2008, p. 102) and there were calls to increase medical sociology input in the training of public health practitioners not only in the United States (Gordon and McFarlane 1996) but also in Canada (Massé and Moloughney 2011) and elsewhere. I return to this issue later.

Sociological theories and public health

Historically, the twin theoretical roots of sociology are philosophy and science as they developed in the seventeenth and eighteenth centuries in Europe with the writings of thinkers such as Charles Montesquieu (1689–1755) and Jean Jacques Rousseau (1712–1778) on social forces, power, and social facts; Immanuel Kant (1724–1804) on the systematic analysis of cause and effect; and Henri de Saint-Simon (1760–1825) about industry, the need for social reforms, and the scientific study of society and social life. Philosophers such as René Descartes (1596–1650), Thomas Hobbes (1588–1679), and John Locke (1632–1704) aimed at 'grand, general, and very abstract systems of ideas that made rational sense', but other thinkers were more concerned with testing those ideas against their 'real world' experiences or more specifically, 'to combine empirical research with reason' following the path of science (Ritzer 1992, pp. 6–11). The latter trend 'led to the application of the scientific method to social issues' seeking to identify possible laws governing social behaviour just as Newtonian physics demonstrated that physical laws rule the physical world (Ritzer 1992, pp. 10–11). This embryonic tension and subsequent symbiosis between the two approaches—a purely theoretical outlook vis-à-vis the imperative to test assumptions empirically—remain at the core of sociology as a field of knowledge today.

Sociology grew from those early ideas into a distinct discipline in the context of wide-ranging social change. Two founding fathers of the discipline were born at the time of the Industrial Revolution and the rise of capitalism in the nineteenth century.

The first was the French thinker August Comte (1798–1857) who contributed his treatise on a new discipline that he labelled 'sociology' and envisaged it as the systematic analysis of society following the model of physics. The second pioneer thinker was Comte's compatriot Emile Durkheim (1858–1917), who promoted the symbiosis of theory and empirical research. Durkheim paid particular attention to, on the one hand, the study of disorder, conflict and its consequences in society; and on the other hand, to the importance of social facts for the study and planning of social reform to reduce social disorder. Durkheim 'legitimized sociology in France' (Ritzer 1992, p. 17). Durkheim's treatise on the systematic analysis of social facts and his study of social factors associated with suicide are seminal works in sociology. Two of Durkheim's most influential books are *Suicide* (1897/1951), demonstrating the link between individual behaviour and society's socioeconomic conditions, and *The Rules of Sociological Method* (1895/1964). Durkheim's emphasis on both sociological theory and empirical research paved the way for today's evidence-based research. His conceptual contribution on the notions of 'the socially normal and abnormal' set the path for 'twentieth century medical sociology' along 'the enlightenment inspired normal/pathological bifurcation in medicine' (Thomas 2012, p. 216).

Two other pioneers in sociology were German: Georg Simmel (1858–1918) and Max Weber (1864–1920). Simmel and Weber were cofounders of the German Sociological Society. Simmel's key contribution is his notion of reciprocity and uncertainty in social interaction (Gerhardt 1989, p. 17). Max Weber's theory of social action, authority systems, and bureaucratization, are among many other seminal contributions in his large body of work, and form part of the foundation of contemporary sociology (Ritzer 1992, pp. 25–29). Among Weber's contributions is his ground-breaking theory of social action and social systems (1921/1968), a classical theory in sociology. In medical sociology, Weber's conceptual contributions are applied to a wide range of studies including, for example, the analysis of the bureaucratization of healthcare systems and organisations (Fox 1989; Germov 2005), the analysis of power and authority of the medical profession (Starr 1982; Freidson 1988); and the impact of life chances and lifestyle on health-related behaviour (Cockerham 2010b).

The body of theory in sociology has grown exponentially over the past century. Sociological theories may be classified into two types: general theories that address all human behaviour and have 'universal' applicability; and 'middle-range' theories that have limited applicability. The most relevant general theories for the sociological analysis of health and illness are: structural-functional theory, symbolic interactionism, conflict theory, and phenomenology/ethnomethodology. Given the space constraints of this chapter, only the general theories are discussed.

The structural-functional theory (now neo-functionalism) is the contribution of American sociologist Talcott Parsons (1937). This theory addresses societies as social systems and proposes that all components of society whether they are individuals, groups, communities, nations, or global organizations, have functions—both manifest and latent—for their maintenance and growth. The dominant trend in social organizations, groups, and social interactions is the maintenance of balance or equilibrium. Consequently, conflict is considered dysfunctional to the development of organizations and social relationships, and dysfunctions need to be rectified or balanced through normative values and

the correction of unanticipated consequences of action (Ritzer 1992). Parsons (1937) approached the analysis of health-related phenomena from the perspective of structural-functionalist systems theory, offering two 'models of illness': the 'deviance' model and the 'sick-role' or 'capacity' model, both of which incorporate the micro- and macro-levels of the social structure. The 'deviance' model presents illness as a state of dependency for the person affected whereby therapy is expected but seen as a social control system and the physician as an agent of social control. The 'capacity' model proposes that illness is a breakdown of normality leading to the individual's total or partial incapacity to perform normal social roles, and brings the person into the 'sick-role'. The sick-role is a social position with different rights and obligations within the social structure that includes the doctor-patient interaction and the doctor's role with specific rights and obligations (Parsons 1937; Gerhardt 1989, pp. 1–67).

The second influential general theory is symbolic interactionism. It proposes that the individual's subjective perception of the situation through meanings and symbols has a significant impact on his/her behaviour. In contrast to structural-functionalism that is predominantly associated with one theorist—Talcott Parsons—symbolic interactionism represents the conceptual contributions of several theorists and offers two models of illness: the 'labelling' model and the 'negotiation' or 'crisis' model. The labelling model proposes that illness may be socially defined or labelled through a process of normative evaluation. Correspondingly, the negotiation model proposes that patients have control over their illness through negotiation: diagnoses and treatments by the medical profession may be negotiated and treatment involves the patient's active participation (Gerhardt 1989, pp. 73–173). Some analysts consider symbolic interactionism as playing an important part in current medical sociology through qualitative methodological designs such as participant observation (Cockerham and Scambler 2010, p. 8).

Conflict theory is the third general sociological theory of relevance for public health. It proposes that the potential for conflict is a normal component of social relationships, thus, negotiation and bargaining are key elements of social interaction. When applied to health phenomena, conflict theory offers two models, the 'loss' or 'stress' model and the 'domination-deprivation' model. The 'loss' or 'stress' model proposes that there is a strong connection between stress and illness; the loss of required social support increases the likelihood of illness; and vulnerability to illness is unequally distributed in society. The body of sociological research on the stress-illness connection was initiated in the 1950s and continues growing today (Pearlin 1989; Thoits 2010). The 'domination-deprivation' model argues that the medical profession occupies a dominant position in society by virtue of its expertise vis-à-vis the patient's position of dependence given the patient's lack of specialized knowledge. The domination-deprivation model is also applied to the analysis of social inequality and socioeconomic deprivation in society (Gerhardt 1989, pp. 249–348). Conflict theory as a school of thought has been particularly influential in the analysis of health policy: 'one of conflict theory's most important assets for medical sociology [is] the capacity to explain the politics associated with health reform' (Cockerham and Scambler 2010, p. 10).

A fourth theoretical position is that of phenomenology/ethnomethodology which proposes, as Ritzer (1992, p. 388)

summarizes it, that 'people are the product of the very society they create'. This phenomenology model regards illness as belonging to 'a broad category of disturbing occurrences. . . which breach the taken-for-granted peace of everyday routines' (Gerhardt, 1989, p. 190). Compared to the other theories, and particularly, to the abundance of empirical research generated by the other three conceptual orientations—structural-functionalism, symbolic interactionism, and conflict theory—the phenomenology/ethnomethodology school of thought has contributed relatively less to empirical research in medical sociology (Cockerham and Scambler 2010).

Sociological research relevant to public health

At the most abstract level, there are two distinctive contributions of medical sociology to the study of health and illness in general and public health in particular. The first contribution is the systematic examination of the link between individual and community and 'the social organizational factors that shape the behaviour of groups' (Thorlindsson 2011, p. 21). The second main contribution is 'that health care systems are organizations . . . embedded within larger institutions, which have been shaped by historical precedents and operate within a specific cultural context' (Quadagno 2010). Medical sociology research relevant to public health can be found within the framework of these two key contributions. The most significant social aspects that exemplify the link between individuals and groups in the context of public health are cultural and social class influences on health-related behaviour of individuals and communities; lifestyles; and the creation and transformation of healthcare systems. Cultural values rooted in ethnic and religious ethos together with social class differences shape people's beliefs and attitudes on health and illness and their lifestyles. Healthcare systems originate, develop and change as part of the interplay of socioeconomic, cultural, and political factors. Let us discuss each of these aspects—culture, lifestyle, social class, and health systems—in more detail.

Culture and public health

Culture is a key term that refers to values and beliefs emanating from one's ethnic and/or religious ethos, typically transmitted across generations as part of the community's identity or 'design for living'. In addition to the influence of the physical and socioeconomic environment on the risk of infectious diseases (Armelaos and Harper 2010) and chronic illness (Charmaz and Rosenfeld 2010), the impact of culture on public health is manifold and it is manifested in at least three main ways: health behaviour, that is, what people do regarding health risks; health attitudes and beliefs, that is, how people feel and think about health and illness; and people's perceptions of and responses to health authorities' public health guidelines and recommendations (Fox 1989; Quah 2007a, 2007b, 2010). Perhaps the best example of this threefold impact is the influence of cultural and/or religious norms and traditions on people's food preparation and diet. Irrespective of what public health authorities advise on food consumption (Harvey 2008, p. 62), ethnic and/or religious groups differ in this regard as they tend to follow their traditionally sanctioned diet, such as vegetarian cuisine, avoidance of pork, the use of animal fat or refined vegetable oils in food preparation, or the avoidance of fried food

at all; preferred beverages; and level of sugar consumption, among other aspects (Seow 2008, p. 193; Cockerham 2010b, pp. 29–32; Idler 2010).

Cultural norms and traditions also guide people's preference for some types of health services over others. For example, cultural healing traditions such as traditional Chinese medicine and Ayurveda represent, respectively, essential aspects of Chinese and Indian cultures and thus the population's preference for and use of these therapeutic practices must be taken into consideration in public health policy (Quah 2003, 2008; Etkin et al. 2008).

Yet another contribution of medical sociology research on the impact of culture on public health and the wider healthcare system is the analysis of the provision of healthcare from two perspectives: the micro-cosmos of clinician–patient interaction, and its permutation into the macro-cosmos of the interaction of health authorities with communities and groups. Two examples suffice. It has been found that social stereotypes held by practitioners (whether clinicians or public health practitioners) distort clinical decisions and interactions with their subjects of care and lead to linking 'certain diagnoses to certain patients' (Smith et al. 2012, p. 162). The second example is a related version of the latter phenomenon: the impact of 'medical constructs', that is, when a physical or mental condition is defined by the health authorities 'as a "disease"' while the same condition is considered normal by the community or at least not a condition that requires medical attention. When this clash of the expert versus lay interpretations occur, the official classification 'has consequences for the social legitimacy of the symptoms, access to treatment, and costs to the health care system' (Conrad and Barker 2010; Rosich and Hankin 2010, p. S4). One illustration of this problem from the field of epidemic prevention is the opposition to mandatory culling of poultry or livestock by some farming communities who fail to appreciate the connection between disease and the destruction of what for them are healthy farm animals and their families' source of livelihood (Quah 2007a).

Lifestyle and health

Medical sociology research provides evidence of another significant influence—related to but distinct from culture—on what people do about health risks: their lifestyle. Cockerham, (2010a, p. 159) defines health lifestyles as 'collective patterns of health-related behaviour based on choices from options available to people according to their life chances'. Life chances is a concept proposed by Max Weber (1968) to represent choices, that is, opportunities and constraints imposed on individuals by their relative position in society. People's lifestyle shapes their patterns of leisure and physical activity: some people have no time for leisure; others are sedentary or engaged in extreme sports; some frequent gyms as networking and thus do regular exercise; others are regularly involved in alcohol drinking, cigarette smoking, and/or hard drugs consumption. Likewise, a person's lifestyle is associated with the risk of serious injuries and the likelihood of contracting infectious diseases. Consequently, it is not surprising to find persistent differences in morbidity and mortality across ethnic groups that are basically of social rather than biological or genetic origin (Krieger 1987; Link and Phelan 1995; Anderson and Whyte 2008; Williams and Sternthal 2010). Considering that lifestyles vary for men and women particularly in Asia, gender differences are clearly discernible in morbidity and mortality figures

(Quah 2011). The importance of culture for public health policy and practice is becoming better recognized and has led some analysts to recommend that public health practitioners be equipped with 'cultural competence' (Perez and Luquis 2008; Waters et al. 2008).

A person's lifestyle is shared and reinforced by his/her social network. Medical sociology research demonstrates the active link between social relationships—also known as social ties—on the one hand, and health behaviours and outcomes on the other hand (Umberson and Montez 2010). Social ties and social networks significantly influence health-related behaviour leading to obesity, cigarette smoking, 'recreational' drug use, and alcohol consumption, among other risk behaviours (Cockerham 2010a; Jones et al. 2011). However, while the most visible influence of social networks on health is negative, social networks can be mobilized in public health policy for the promotion of healthy habits and health risk-avoidance in the community (Mechanic and Tanner 2007; Umberson and Montez 2010; Brown et al. 2011).

Social class, social stratification, and public health

Social class, a fundamental sociological construct, depicts the relative position of an individual in the social hierarchical system of prestige in his/her society (Weber 1968). In sociological research, a person's social class—socioeconomic status or SES—is ascertained by means of a composite index of three or more indicators, the most common of which are personal income level, years of formal education completed, and occupational prestige.² The resultant SES scores may be used as a continuous scale (usually standardized scores ranging from 0 to 100) or as a set of discrete categories based on the arithmetic mean and standard deviation. The simplest presentation of SES scores is a three-level description of lower class, middle class, and upper class. However, quantitative and continuous SES scores are preferred in sociological studies of class differences and patterns of stratification in society (Bendix and Lipset 1966; Nam and Powers 1983; Phelan et al. 2010).

The nearly universal phenomenon of social class differences influencing the person's access to and utilization of healthcare services is supported by sociological research findings: the higher a person's social class, the greater his/her access to healthcare services (Heggenhougen and Quah 2008; Lahelma 2010; Rosich and Hankin 2010; Brown et al. 2011). A country's socioeconomic conditions lead to 'persistent health inequalities among social groups' (Rosich and Hankin 2010), inequalities which normally are 'deeply rooted in society' (Phelan et al. 2010). Research findings indicate that social class reinforces the influence of lifestyle on health behaviour. However, under certain conditions, social class—mostly due to the influence of education and occupation—may have a stronger impact than cultural beliefs and norms on health behaviour, on access to health services, and on a person's exposure to occupational hazards. Indeed, workers have differential exposure to dangerous repetitive tasks, risk of industrial accidents, and environmental pollution, among other health risks embedded in the nature of the job. Consequently, sociologists examine the health impact of each SES component separately: occupational prestige, income level and educational level as well as the strength of SES as a predictor of health behaviour.

The influence of social class on health status, health behaviour, access to and use of health services, is one of the earliest

and most examined social influences on health. Summarizing the advances of medical sociology in the study of social class and health in the last fifty years, Phelan et al. (2010, p. S29) report that their data support 'the theory of fundamental causes'. This theory states that social class 'influences multiple disease outcomes. . . through multiple risk factors'; impacts 'access to resources that can be used to avoid risks or minimize the consequences of disease once it occurs'; and that those influences tend to persist over time. Their research findings support the theory and have implications for public health policy that are different from results in studies applying 'an individually oriented risk-factor approach'. Thus, these authors recommend that social class-induced health inequalities 'can be reduced by instituting health interventions that automatically benefit individuals irrespective of their own resources or behaviors' (Phelan et al. 2010, p. S37).

Two additional contributions of the sociological study of occupations and professions that increase our understanding of health and illness in society are the analysis of occupational hazards and the role of the medical profession. On the one hand, the comparative analysis of health outcomes, disease prevalence and disease incidence across the wide spectrum of occupations in society consistently reveals clear variations derived mainly from the nature of work performed and occupational hazards (see, e.g. Christ et al. 2012). On the other hand, sociologists also examine the biomedical profession and traditional healing occupations in terms of their relative prestige, their training, internal composition and dynamics, and their impact on the health of populations (e.g. Starr 1982; Freidson 1988; Quah 2003, 2008). Research findings indicate that the ideal trust-based and confidential doctor–patient relationship is corporatized today as the medical profession is overwhelmed by 'the healthcare industry' dominated by employers' 'guidelines, pre-authorization, centralization and financial awards for increased output' (Starr 1982; Freidson 1988; Timmermans and Oh 2010; Vanderminden and Potter 2010, pp. 356–7).

Healthcare systems and public health

In addition to the analysis of the impact of culture and social class on public health, another illustration of the contributions of medical sociology is the study of the nature, dynamics, and evolution of healthcare systems at the national and transnational level. When sociologists study healthcare systems they include the approaches taken by nation-states towards the creation, organization, distribution, and management of their healthcare resources. Thus, health policy and healthcare reform are integral parts of this type of studies. Some cross-national and comparative research findings on healthcare systems suggest that in many countries today 'too much priority has been given to hospital care at the expense of the development of primary care, community care and public health' (Stevens 2010, p. 435).

One of several aspects of healthcare systems that have received increased attention by medical sociologists in the past decade is the analysis of flaws in health systems that distort the link between cost and utilization of health services, thus the urgency of healthcare reform (Mechanic and McAlpine 2010). One sector of the healthcare system that has a significant input in healthcare costs is the role of stakeholders such as the pharmaceutical industry in the promotion of medicalization, particularly through the use of market opportunities and marketing methods to sell their products (Rosich and Hankin 2010, pp. S4–S5).

Another illustration of medical sociology analyses of health systems is the area of health services research. There is a vast literature of studies documenting the influence of social class and ethnic differences on unequal access to and utilization of health services. Three types of studies illustrate this research area. The first type of study shows that unequal access to healthcare services is preserved by institutions and policies that constrain and enable 'the actions of health services organizations, health care providers, and consumers' (Wright and Perry 2010, p. S109). Those studies of multiple dysfunctions of health systems challenge international policymakers and are the subject of social policy interventions based on social science research such as the Disease Control Priorities Project jointly conducted by the World Health Organization, the US National Institutes of Health, and the World Bank (Laxminarayan et al. 2006). The second type of health systems research study is the comparative analysis of health financing approaches and systems in terms of their suitability to the socioeconomic needs and demographic characteristics of the population. One example of this type of research is the study of insurance plans by Zaslavsky and Epstein (2005). The third type of study represents the direct input of medical sociologists on public policy; one recent example is the analysis of changes in state regulations on the collection and access to health relevant population data for research purposes (Hynes 2011).

In addition to the relevance of the analysis of culture, lifestyle, social class, and social systems for public health, medical sociology also examines the interaction of these and other factors in the analysis of disease incidence and prevalence in the community. For example, Anderson et al. (2011, p. 390) found that 'social, cultural, and biological issues should all be considered in the assessment of differences in breast cancer survival'. Brown et al. (2011, p. 941) discuss the relevance of social factors in the diagnosis and management of obesity, diabetes, and asthma. A wealth of studies on the social factors of disease is found in medical sociology journals mentioned earlier such as *JHSB*, *SSM*, and *Sociology of Health and Illness* and numerous other international refereed journals on health research.

Sociological research methods and public health

Medical sociology applies the full range of sociological approaches and methodological tools to the study of socioeconomic, cultural, and demographic characteristics of populations and individuals that impact their health (Rosich and Hankin 2010; Smith et al. 2012). Indeed, referring to the analysis of epidemics and health behaviour in general, Hedges et al. (2002) argue that 'social science knowledge in theory and methodology has guided public health research for several decades'. One illustration of this influence is the application of sociological approaches to the analysis of income inequality and health in most of the articles compiled in the book on that topic by Kawachi et al. (1999).

The fundamental position of sociology in general, and medical sociology in particular, regarding scientific research is well articulated by Vogt (2007, p. 5) when he highlights the critical tasks of collecting and analysing evidence for the purpose of creating knowledge. In this regard, there is clear compatibility between the goals of research in both fields of knowledge, medical sociology, and public health. Still, there are three important characteristics

of sociological research methodology that must be taken into consideration: (1) the kinds of data used in sociology, (2) the levels of measurement applied, and (3) the types of research design followed. Let us consider each characteristic in turn.

What kinds of data are used in sociology? Two kinds of evidence or data are used: *primary* and *secondary* data. Primary data are data collected first-hand by the investigator, for example, data on people's attitudes and behaviour obtained through personal interviews, observation, experiments, or surveys; or data extracted by means of first-hand analyses of documents, letters, records, or other types of 'raw' data. In contrast, secondary data are data previously collected by others, for example, official statistics, population censuses, or databases with processed or coded data sets from surveys or completed studies. Many research institutions keep databases of secondary data, usually codified data from survey research studies that can be purchased by other researchers together with the respective codebook for secondary and longitudinal analyses (Miller and Salkind 2002, pp. 346–53). Many data archives are now accessible online.

What levels of measurement are used in sociology? Sociological research uses four levels of measurement: nominal, ordinal, interval, and ratio levels. The most rudimentary is the *nominal* level which uses names or labels to depict different categories of the phenomenon under study (e.g. the labels 'male' and 'female' to record a subject's gender; the labels 'Muslim', 'Hindu', 'Christian', 'other religion' and 'no religion', to record the subject's religious affiliation). Each name or category may be assigned a numerical code but the numbers have no quantitative meaning, they are only labels. *Ordinal* measurement assigns ranks to categories of the observed phenomenon (example: 'slender', 'plump', 'obese' to record body appearance) but 'the distances between ranks in an ordinal scale are not necessarily equal'. *Interval* measurement uses ranks with a standard and measurable distance between categories but 'have no meaningful zero point'. The typical illustration of an interval level of measurement is the Fahrenheit temperature scale. A common sociological example is the range of a person's attitudes towards a problem or situation. Here are two sociological interview questions that illustrate the *interval* scale: 'Would you say you are very confident, only slightly confident, slightly anxious, or very anxious about what needs to be done to handle the patient?'; 'How would you rate your quality of life? "Very poor", "Poor", "Neither poor nor good", "Good", or "Very good"?'. Yet another illustration of interval scales is the questionnaire used for the analysis of people's 'quality of life' comprising the Quality of Life scale by the World Health Organization (2004). The interval scale is more accurate than the nominal or ordinal levels of measurement, but less precise than the *ratio* scale that has both 'equal intervals between categories and a true zero point' (Vogt 2007, pp. 9–10). Examples of ratio scales in sociology are: the measurement of the subject's age in years, income in dollars earned per month, formal education in number of years of completed schooling, number of children, and years of marriage.

What types of research designs are used in sociology? Depending on the nature of the phenomena under investigation and on the investigator's preferred level of measurement, sociologists may use qualitative or quantitative designs or a combination of both. Researchers who have a preference for qualitative research tend to steer clear of measurement altogether or use only nominal levels of measurement. Some of the most common qualitative research

designs are participant and non-participant observation of social phenomena, and conversations with research subjects individually or in small groups (Schwartz and Jacobs 1979). One modality of the small-group method is the focus group approach whereby the researcher, acting as moderator, gathers together a small group of people—preferably not acquainted with each other—to discuss a particular topic. The focus group method is probably the weakest approach and it should be used with extreme caution and perhaps only in exploratory research, due to its three most serious limitations: (1) considering that the conversation is public, that is, in front of strangers, the researcher cannot guarantee confidentiality to the focus group participants, but confidentiality is an important component of informed consent required when conducting research with human subjects (Citro et al. 2003); (2) the validity and reliability of data collected in focus group discussions are low or non-existent; and (3) focus group participants are typically influenced by social pressure given the dynamics of small-group interactions.

In contrast to qualitative designs, a quantitative research design may involve all four levels of measurement but mostly interval and ratio levels of measurement of social phenomena. Similarly, a quantitative research design may include one or more methods of data collection: document analysis, observation, personal interviews with structured or unstructured questionnaires, surveys, experiments or quasi-experiments (Boudon 1993, pp. 158–71; Vogt 2007, pp. 8–10). Naturally, as it happens in all fields of knowledge, research methods have their limitations and researchers need to consider the suitability of the methods selected and take steps to reduce as much as possible the probability of error. With the objective of error reduction in mind, medical sociologists may use in the same study a combination of methods from the array available: participant and non-participant observation; in-depth unstructured interviews; and structured interviews using questionnaires with a variety of question formats, from open-ended questions to attitudinal scales. Structured questionnaires are usually the main instrument of data collection in survey research. Survey research is a methodological design in sociology created by Paul Lazarsfeld (Boudon 1993). A prominent sociologist, Paul Lazarsfeld (1901–1976) identified three phases in the history of surveys. The earliest phase was before 1930, when surveys were used for 'the collection of factual information which could help to improve social conditions'. The second phase covered the period 1930 to 1948 when surveys were used to collect data on public opinion and consumer preferences. The third phase, from 1949 onwards, started with the publication of the seminal sociological study *The American Soldier* when the survey method became an important sociological tool for the collection of 'a large body of data' that could be 'made coherent and meaningful by careful statistical analysis' (Lazarsfeld 1968, pp. vii–x; Boudon 1993).

Sociologists using quantitative research methods aim to ascertain and reduce the level of error in the calculation of correlations among phenomena and in inferences drawn from representative samples to the total population (inferential type I and type II errors). This objective is facilitated by the application of statistical analysis models ranging in complexity and sophistication from simple measures of association such as chi-square, Pearson's coefficient, analysis of variance (ANOVA) and path analysis, to multilevel models such as ordinal logistic regression, structural equation modelling, and hierarchical linear modelling, among

others. Examples of some of the most recent medical sociology studies applying multilevel models are: the impact of alcohol drinking on academic performance of secondary school students (Crosnoe et al. 2012), perceived discrimination and health among adolescents and young adults (Grollman 2012), the influence of social networks in the management of hypertension (Cornwell and Waite 2012), and factors leading to sleep disturbance among US adults (Ailshire and Burgard 2012).

Another important aspect of sociological research that must be mentioned is the commitment that mainstream sociology shares with all other fields of scientific research: to pay serious attention to data validity and reliability. Reliability means consistency in the measurement: getting the same results every time the phenomenon is measured with the same instrument. The relation between validity and reliability is important: a reliable instrument may have low validity (Vogt 2007, p. 118). Validity has two general dimensions: internal and external. Internal validity focuses on the research question. The most elementary form of internal validity is content validity and it addresses the question: is the instrument measuring what it intends to measure or something else? There are two additional types of internal validity: criterion-related validity and construct validity. The second dimension is external validity; that is, 'the potential for a study's findings to be generalized from one setting to others' (Burchett et al. 2011, p. 238).

This brings us to the matter of sampling. From the perspective of public health, perhaps one of the most relevant methodological features of sociology, and in particular, medical sociology, is the study of population trends through the analysis of representative samples, also known as probability samples. A representative sample is a sample drawn from the target population following a procedure that gives each individual in the target population the same probability of being selected. Probability samples allow the researcher to make inferences to the total population while non-probability samples do not. The application of inferential statistical tests such as chi-square, *t*-test, and ANOVA indicate the probability that what was found in the sample does not reflect the situation in the population but it is due to chance or sampling error (Neuman 2000, p. 217; Vogt 2007, p. 12).

On the matter of sampling, two caveats are in order. The first caveat is that there are research topics and research situations for which random sampling is impossible to obtain or is unsuitable. This is the case of health conditions socially seen as stigmatizing, or deviant, so that the affected subjects and/or their families refuse participation in the study; or there is no comprehensive and reliable record of all members of the target population that could be used as the sampling frame to draw a random sample. In situations like these, the researcher may opt for a non-probability sample.

The 'purposive sample' is one form of non-probability sample whereby subjects are selected based on specific criteria, rather than randomly (Vogt 2007, p. 81). Naturally, non-probability samples preclude any inferences to the total population as only a probability sample has external validity (Vogt 2007, p. 82).

The second caveat is on the size of the sample. Besides the options of representative or purposive sampling of large populations, there is also the case study approach whereby the researcher studies only one or a few 'cases' of the social phenomenon under investigation. This approach is useful in at least two ways. First, in emergency situations, a case study may be conducted when rapid

information about a condition is required, for example, the case study of a person or a family affected by a rare or 'new' illness that may be potentially contagious; or a unique event that could seriously affect large numbers of people. Second, in non-emergency situations, a case study approach is commonly used in exploratory research: that is in situations where the social phenomenon is new or never studied before and the researchers wish to familiarize themselves with the nature of the phenomenon in order to plan a more comprehensive and systematic study (Ragin and Becker 1992).

Psychology in public health

It is generally agreed that the discipline of psychology was born in the late nineteenth century (Norcross and Karpiak 2012) as a continuation of the discovery of 'the neurophysiological location of psychological faculties' among other advances in the study of the human body (Greenwood 2009). The period 1890–1910 was particularly fruitful for the discipline: it produced the seminal book *Principles of Psychology* by American William James in 1890, and Sigmund Freud's *Die Traumdeutung* published in 1900, often deemed as the framework of psychoanalysis and of Freud's subsequent studies of the thread linking personality, mind, and illness (Friedman 2002).

Just as the subfield of medical sociology plays an important role within the discipline of sociology, the most relevant area of specialization in psychology for public health is health psychology (Luecken and Gallo 2008). Health psychology is also referred to by some analysts as clinical psychology or clinical health psychology (Boyer and Paharia 2008), and as a distinct and growing subfield (Romanow and Marchildon 2003). Health psychology has a relatively recent history (Albery and Munafò 2008). Introducing his *Health Psychology* textbook, Howard S. Friedman wrote that although health psychology has 'its roots in the fields of medical sociology. . . public health' and other fields, 'until the late 1970s, there were no programs of study in health psychology' (Friedman 2002, p. 23). The formal introduction of health psychology as a subdiscipline of psychology is highlighted by three chronological signposts: 1974 when health psychology was first proposed as a new subject in the curriculum at the University of California–San Francisco School of Medicine; 1977 when Health Psychology was approved as a new division of the American Psychological Association; and 1984 when the 'First International Symposium of Health Psychology' was held (Stone 1991, p. 3). As Friedman reports, the number of health psychologists has been growing rapidly not only in the United States but in many other countries (2002, p. 23).

However, until about one decade ago health psychology had traditionally 'maintained. . . a pronounced unidimensional focus on mental health' (Arnett 2001, p. 38). Arnett argued that the field of health psychology 'would be significantly enhanced by a more comprehensive understanding of the epidemiology, pathophysiology, and natural history of the wide range of health disorders amenable to psychological interventions' (Arnett 2001, 43). Among the health areas that Arnett suggested could be studied by health psychology—in addition to mental health—are weight control, and addictions to alcohol, nicotine, and hard drugs (Arnett 2001, p. 41). Health psychology has developed significantly since the 1970s although at different paces in different countries. Sweden

is seen as a pioneer based on the development of ‘psychophysiology of stress at the Karolinska Institute in Stockholm’ in the early 1970s (Stone 1991, p. 9).

Psychological theories and public health

One of the best known names in the history of psychology is Sigmund Freud (1859–1939). Freud was trained as a physician. He launched a new ‘school’ of psychoanalysis in psychology with his colleague Joseph Breuer promoting the idea that neuroses had a psychological, not a physiological basis (Ritzer 1992, p. 32). Freud based his theories on his observation of patients, making general inferences from individual cases.

In its early development, psychology had a similar concern found in sociology: a positivist trend following the goals of science, to identify universal laws ‘expressed in theories that allowed prediction and explanation’ (Looren de Jong 2010, p. 746). Over the years this quest promoted a range of theories including psychoanalysis, neuropsychology and various personality theories some of them spanning the disciplines of sociology and psychology, usually clustered into four groups. These clusters are: (1) social cognition models addressed to the explanation of individuals’ health-related behaviour and comprising the theory of planned behaviour, the health belief model, the trans-theoretical model, and the health action process model; (2) self-regulation models focus on risk behaviours and include cognitive adaptation theory, the self-regulation model, and the model of self-efficacy; (3) the psycho-physiological models cluster that ‘describes how psychological processes, particularly in response to stressors, can influence physiological functioning’, and includes the gate control theory of pain, the cognitive perceptual model, and the general adaptation syndrome, among others; (4) the fourth and final cluster is the environmental models cluster that includes the operant learning theory, conservation of resources theory, and the demand-control model of work stress (Weinman et al. 2007a, xxx–xxxv). Given the space constraints of this chapter, this is only a summary of the main theories but it conveys the idea of the large and growing array of conceptual perspectives underpinning research in psychology today. Marshall H. Becker and his colleagues (Becker et al. 1977/2007) provide an excellent discussion of the conceptual collaboration between sociology and psychology in the analysis of health behaviour and the fruits of that collaboration in the form of conceptual models and abundant research.

Seen from a different and more abstract perspective, psychology—and all its subfields including health psychology—is engaged in a debate between two contrasting positions: a contemporary version of the positivistic approach termed ‘rational reconstruction and theory building’ and ‘critical deconstructivism’. The latter approach ‘focuses on theory as dialogue and critique’ and on ‘the collective construction of meaning, not the discovery of objective facts about the mind’ (Looren de Jong 2010, 747–8). The two positions are seen as the bases for ‘two research traditions within academic psychology, that is, social constructionism and cognitive neuroscience’ (Praetorius 2003).

The debate over theoretical paths that can strengthen psychology’s contribution to science and psychologists’ professional identity continues unabated (Romanow and Marchildon 2003), but it has produced some intermediate schools of thought that

coexist with ‘mainstream psychological research’ (Looren de Jong 2010). At the same time, some psychologists like C.R. Cooper and J. Denner have recommended the inclusion of culture in the discipline’s research repertoire acknowledging that culture affects behaviour. Their recommendation springs from the engagement of psychologists in interdisciplinary research and the fact that culture is a long-standing subject of investigation in sociology and other social sciences but has not received sufficient attention in psychology (Cooper and Denner 1998). Another reason is their concern with the problem of external validity in psychology. They wrote, ‘Psychologists continue to generalize beyond their samples; while studying only their own countries. . . they assume that psychological phenomena are universal enough to make such studies representative’ (Cooper and Denner 1998, p. 579).

Psychological research and services relevant to public health

The general scope of health psychology research was well delineated by Canadian psychologist John L. Arnett (2001, p. 45) thus: ‘the diagnosis and prevention of illness, the promotion of health, and the amelioration of suffering related to the whole range of health conditions. . . across the whole spectrum of health’.

Clinical/health psychologists provide direct healthcare but their actual clinical practice is determined by government regulations and, more broadly, by the political system and ideology guiding the healthcare system. American psychologists succeeded in obtaining official licensing and getting federal statutes modified ‘to gain autonomous inclusion in most federal programs’ providing paid healthcare and to practise in managed healthcare organizations. However, for most of the twentieth century, the training and practice of psychology and health psychology did not attend to the profession’s participation in the public policy process or in ‘programs that. . . address society’s public health priorities and perceived needs’ (DeLeon et al. 1995, p. 493). This situation is common in other countries but it has been changing. For example, in most OECD (Organization for Economic Cooperation and Development) countries, people have access to paid psychotherapy services only if provided by physicians specialized in psychiatry. However, while both psychologists and psychiatrists can provide psychotherapy, ‘PhD-level clinical psychologists receive far more extensive training and education in psychotherapy than physician-trained psychiatrists’ (Romanow and Marchildon 2003, p. 286). In the realm of ideology, in countries with ‘centralized planning for healthcare’ or in community-based healthcare programmes such as Cuba, Costa Rica, and India, ‘the concept of health psychology appeared early and its approach tended to be community-oriented’, in contrast to the individual orientation of the field in the European tradition (Stone 1991, pp. 12–13).

The practice areas among health psychologists also vary across countries. In the first two decades of the field, while clinical work was the most common area of activity in the United States and the United Kingdom, the main work of health psychologists in Germany, Austria, France, and Argentina was teaching at medical schools (Stone 1991, p. 10). An overview of current health psychology work relevant to public health is suggested in the 2010 study of American health psychologists by Norcross and Karpiak (2012). These researchers found that the most common area of professional work among American health psychologists is psychotherapy

practised either on individuals or as group therapy. Indeed, 76 per cent of the professional health psychologists spent about 35 per cent of their professional activity in psychotherapy in 2010, and it has been the most common area of work since 1986 when comparative data collection started. The four other main professional activities are: diagnosis/assessment (58 per cent), teaching (49 per cent), clinical supervision (47 per cent), and research/writing (47 per cent) (Norcross and Karpiak 2012, pp. 5–6).

Psychologists propose that some of the services they offer do increase the productivity of health services by lowering public health expenditure. One illustration of this type of services is the provision of individual or group psychotherapies for breast cancer patients, and the treatment of depression and addiction-related conditions through cognitive behaviour therapies (Romanow and Marchildon 2003). Another example is ‘evidence-based parenting interventions’ to assist parents with the effective management of children and adolescents affected by ‘behavioural and emotional problems’ (Sanders, 2010). In his Presidential address to the Canadian Psychological Association, M.R. Sanders suggested that psychologists could offer evidence-based parenting interventions as a ‘public health approach’ because the aim of his proposal was ‘to reduce the prevalence rates of inadequate parenting at . . . [the] . . . population level’, a drastic departure from the traditional focus of psychology on ‘individual clinical interventions’ (Sanders 2010, p. 17). Similar intervention programmes have been tried in the United States, England, and several European countries.

One of the relevant areas of health psychology for public health is stress management. An interesting input was borne out of the collaboration between a public health practitioner and a psychologist: preventive stress management programmes for corporations based on the ‘theory of preventive stress management (TPSM)’ devised by J.C. Quick and J.D. Quick in 1979 and focused on both physiological stress and organizational stress (Hargrove et al. 2011). According to the TPSM, individuals and organizations react to stressors either positively or negatively. The response to a stressor, or distress, ‘is the psychophysiological response of the individual as well as . . . of a group or organization to fight or to flee’; the outcomes of that response may be ‘either positive, such as a heightened alertness and enhanced performance, or negative, such as medical, psychological and behavioural distress’ (Hargrove et al. 2011, pp. 182–3). As mentioned earlier, research on stress management was one of the earliest contributions in the field of health psychology by Sweden’s Karolinska Institute. Swedish researchers analysed the impact of stressors produced by the individual’s social and physical environment including the work setting, home environment, transportation, and retirement among other factors (Stone 1991, p. 9).

Family psychotherapy is yet another area of psychology that is relevant to public health. It involves various modalities two of which are perhaps the best well known. They are family therapy involving children and adolescents, and family therapy with older adults. Family psychotherapy involving children and youth is typically offered in collaboration with the school system in the community and deals with children’s mental illness as well as with behavioural problems including drug abuse, truancy, and academic performance issues among other aspects. Family psychotherapy involving older adults is gaining ground in countries with a growing elderly population. Psychologists involved in family psychotherapy with older adults deal with a wide range of issues

from dementia and other mental illness to intergenerational conflict, the significance of home setting, pain management, mobility, and physical impairment, among other problems (Curtis and Dixon 2005). In their review of recent developments in family psychotherapy with older adults in the United Kingdom, Curtis and Dixon found ‘a lack of empirical research into family therapy with late life families’ that needs to be addressed and an insufficient number of family psychotherapists doing this type of work compared to the larger number involved in family therapy with children and younger adults (2005, pp. 56–7).

Change in health-related behaviour is another area of work of health psychologists that is relevant to public health. Psychologists apply one or more social cognition theories (used in sociology as well) in individual and group therapy interventions with youth and adults to modify risk-taking behaviours such as alcohol drinking and cigarette smoking, and to reinforce preventive health behaviours such as condom use and healthy diet (Thirlaway and Upton 2009).

Psychological research methods relevant to public health

A distinguishing feature of psychology is its permanent state of critical introspection. This situation applies to its research methodology. Discussing the methodological landscape in psychology, Lambdin (2012, p. 68) argues that a dominant feature is the rift between two camps: experimental psychologists who claim their work ‘is science because it is experimental’ and the work of their non-experimental colleagues. Both psychology camps are searching for ways to advance the discipline and correct research gaps and bias. But, as Lambdin rightly points out, common sources of bias are found in all scientific research—irrespective of the knowledge area, whether it is psychology, sociology, biomedicine, or any other: ‘the results of any study can be preordained by the selection of stimuli, how variables are operationally defined, the construction of the experimental protocol, the level at which the data are aggregated, or the particular analysis the researcher chooses to utilize’ (2012, p. 69). Lambdin suggests that researchers should explain their findings ‘without reference to inferential statistics’; and advises applying instead ‘a lot of hard thinking and critical reasoning’ and focusing on ‘effect sizes and confidence intervals which . . . are together far more informative and meaningful’ (2012, pp. 70–1).

The use of statistical inference is only one of several aspects under discussion within the field of psychology. Four main fundamental issues that impact research are actively discussed today: the ‘scientific versus humanistic’ cultures in psychology; two ontological issues, the ‘subjective–objective’ and the ‘individual–collective tensions’; ‘the problem of evaluative criteria’; and ‘the problem of competing worldviews or value systems’ (Goertzen 2008). The beneficial ongoing debate ranges from critiques of conceptual schools of thought in psychology to practice-oriented assessment of diagnostic material, including approaches to improve the *Diagnostic and Statistical Manual of Mental Disorders*, the internationally recognized prime classification of psychopathology published periodically by the American Psychiatric Association (Acton and Zodda 2005).

Most if not all health psychologists are inclined to see conclusions obtained from an experimental design, also known

as a randomized clinical trial, as significantly better than findings from case studies, but unfortunately it is not possible to use random allocation and true experiments in health psychology (Friedman 2002, p. 21). Thus, in addition to other forms of systematic observation, psychologists have traditionally used attitudinal scales and questionnaires to collect systematic responses from subjects in laboratory situations or one-to-one interviews or small-group contexts. In addition to this long-established psychological methodology, some psychologists may occasionally borrow methods from other fields to study psychological phenomena. For example, in their investigation of people's beliefs about medicine, Kienhues and Bromme (2012) used a survey technique by sending a questionnaire online to 284 higher school students.

The distinction made between quantitative and qualitative methods of research—discussed above—is the same as in sociology. Thus, in general, psychologists have a preference for quantitative methods and for the application of advanced statistical models in data analysis. However, Weinman and colleagues (2007b) suggest that qualitative methods are used now more often than before and discuss several methods that are undergoing improvement. Three examples suffice. The first illustration is studies of health-related behaviour where investigators may use 'self-report, observation by video or audio recording'. Subjects' self-reports are the most common method of data collection in psychology 'but it is open to problems of error and bias'; thus this method is under close scrutiny and efforts are underway to improve it with a view to make it more 'psychometrically sound'. The second illustration is the assessment of stress as the occurrence of negative life events and emotional changes using attitudinal scales such as the 'Impact of Event Scale' and the 'Hospital Anxiety and Depression Scale' or HADS. The third illustration is the measurement of 'health and illness cognitions' such as the perception of health risks through the use of questionnaire scales such as the Multi-dimensional Health Locus of Control scale and the Illness Perception Questionnaire (Weinman et al. 2007b). As is the pattern in sociology, psychologists dedicate considerable effort at examining and improving the validity and reliability of their research instruments (Sutton 2007).

Formalizing the contributions of sociology and psychology to public health training

The relevance of sociology and psychology to public health is amply recognized today not only in public health research and practice but also in public health education, particularly graduate training in public health.

Some researchers maintain that the United Kingdom was the first country to formalize the field of public health (Paccaud et al. 2011, p. 68). It is not surprising then, that the first training programme in public health was launched in 1871 in the United Kingdom. That programme was the Diploma in Public Health comprising only three subjects, 'epidemiology, population statistics and communicable diseases', and given 'a growing interest in how social determinants of health and illness interacted with disease since the 1930's', sociology and psychology were 'incorporated into public health education' in the United Kingdom in the 1960s (Cole et al. 2011, pp. 89–90).

The incorporation of sociology and psychology in public health curricula has been sluggish in European countries but in the United States, two private universities included both fields as the forerunners of graduate training in public health: Johns Hopkins and Harvard (Paccaud et al. 2011, p. 69). The American framework for public health training at the university level—the origins of which can be traced back to the Welch-Rose Report published in 1915—implemented in schools of public health include social and behavioural sciences as one of five core areas of the curriculum. The five areas are required by the Council on Education for Public Health (CEPH) that regulates Masters and Doctoral Public Health programmes in the United States (Gebbie et al. 2007; Calhoun et al. 2011, pp. 152–3; CEPH 2011, pp. 14, 17; Imperato et al. 2011; Rosenstock et al. 2011, pp. 43–6).

The past two decades have seen serious efforts to improve the quality of medical education curricula worldwide (WHO 2005). Other international organizations such as the World Federation for Medical Education are leading the improvement of medical education standards by incorporating in the graduate public health curriculum 'basic biomedical, behavioral and social sciences, general clinical skills, clinical decision skills, communication abilities and medical ethics' (World Federation for Medical Education 2003, pp. 5–10). As part of that effort to improve public health training, the experience of the University of North Carolina–Charlotte (UNC) is illustrative of the trend towards inclusion of health behaviour in the curricula of public health graduate and undergraduate programmes accredited by the CEPH. At UNC the expansion of the public health curricula was motivated by the aim to establish 'a thriving research base that emphasized population health and health behavior research' and 'responsive and progressive health and human service training programmes' within an interdisciplinary model (Thompson et al. 2009, p. 3). The UNC's current 45-credit curriculum for the Master of Science in Public Health consists of professional practice and research in epidemiology, biostatistics, research methods, 'behavioral and environmental determinants of health' as well as programme planning and evaluation; and the core curriculum includes 'Social and Behavioral Foundations of Public Health' (Thompson et al. 2009, p. 6). A case was made as well for the inclusion of health sociology modules in the Columbia University Medical Center's curricula for internal medicine residents to expose them to 'important societal health issues such as health disparities, social determinants of health and health literacy' (Fiebach et al. 2011, p. S268).

Public health programmes in Europe have followed the same trend of incorporating social and behavioural sciences as core subjects in graduate schools of public health following accreditation requirements set by the European Agency for Accreditation in Public Health Education (Otok et al. 2011; Tulchinsky and McKee 2011). Outside the Western sphere, however, the incorporation of social and behavioural sciences into the public health curriculum started only recently. Today, medical sociology and health psychology are standard components of many graduate public health programmes in some non-Western countries (Bangdiwala et al. 2011; Pino and Solimano 2011).

A final word is in order. The development of multidisciplinary research on human subjects involving biomedicine, sociology, and psychology in various combinations, has led regulatory agencies to support collaboration by creating and expanding ethical guidelines. This effort also reinforces the fact that research ethics is as

important in medical sociology and health psychology research as it is in biomedical research. Two of the most relevant dedicated guidebooks have been published by the National Academies Press: *Protecting Participants and Facilitating Social and Behavioral Sciences Research* (Citro et al. 2003) and *Conducting Biosocial Surveys* (Hauser et al. 2010).

Conclusions

The preceding pages present a succinct description of what two social sciences, sociology and psychology, and their respective subfields, medical sociology and health psychology, offer to the discipline of public health. Perhaps the strongest tie binding medical sociology and health psychology is their interest in the systematic analysis of health-related behaviour and their attention to applicability of research findings to the solution of health-related problems in the community.

The essential focus of sociology is on the individual's social behaviour, that is, the person's actions and motives addressed to the actions and motives of others in primary and formal relations, as well as in collective entities ranging from small groups to institutions, social systems, nations, and global organizations. Therefore, medical sociology analyses actions, beliefs, attitudes, and knowledge of individuals on matters of health and illness; health-related activities of groups, organizations, and institutions at all levels of society; and the impact of the socioeconomic, cultural, political, and physical environment upon the actions, attitudes, and beliefs of individuals and collective entities of any size. Consequently, medical sociology involves the study of both the micro-level and the macro-level spheres of social action: from the trilogy of individual action (preventive health behaviour, illness behaviour, sick-role behaviour), to dyads and primary groups (e.g. doctor–patient relations, family's health, impact of small social networks on health risks), to large and complex organizations and social systems (e.g. the analysis of healthcare organizations, insurance and pharmaceutical corporations, the medical profession, government health policies, and impact of ideologies on the distribution of health resources in the population).

Health psychology's original focus was on the analysis of the individual's mental health. However, over the past two decades health psychology has re-oriented its attention to the analysis of all other aspects of health behaviour in addition to and beyond mental illness. This re-alignment of research interests is a positive development for public health because public health practitioners may now benefit not only from the growing body of knowledge produced by medical sociology and health psychology, but they also benefit from the conceptual and methodological expertise of both disciplines.

Knowledge production in the twenty-first century is increasingly leaning towards multidisciplinary collaboration across knowledge domains. This modality presents a unique challenge: multidisciplinary collaboration works well as long as each participating discipline has something distinct to offer to the collaborative enterprise. Each discipline must continue to push the boundaries of knowledge to increase its own expertise. Medical sociology and health psychology continue creating knowledge in their respective areas of interest through research and constant critical examination of their own theories and methodological approaches. At the same time, both disciplines collaborate actively

with each other, with public health, and with other biomedical fields for the improvement of people's health. The collaboration involves both applied and theoretical knowledge. The increasing pace of collaboration among medical sociology, health psychology, and public health is already evident not only in the joint authorship of scientific publications in books and refereed journals, but also in the multidisciplinary composition of the faculty in schools of public health around the world. Indeed, high-ranking public health schools tend to have a greater proportion of faculty from different disciplines.

Notes

1. The name of the ISA Research Committee was changed from 'Medical Sociology' to 'Sociology of Health' in 1986 but the work and objectives of the ISA Research Committee remained the same.
2. Sociological research over the past six decades around the world has demonstrated with systematic empirical evidence a universal phenomenon first hinted at by French sociology pioneer Henri de Saint-Simon in 1819: different occupations are allocated different levels of prestige or deference and rewarded accordingly financially (from low-paid, unskilled occupations such as street cleaners or bricklayers, to high-salary, highly skilled occupations such as neuroscientists). Occupational prestige is measured by means of population surveys whereby each person from a representative sample of the total population is asked to rate in a five-point scale (5 'excellent standing', 4 'good standing', 3 'average standing', 2 'below average standing', and 1 'poor standing') a comprehensive list of occupations in their society.

Sexuality and public health

Richard Parker, Jonathan Garcia,
Miguel Muñoz-Laboy, Marni
Sommer, and Patrick Wilson

Introduction to sexuality and public health

Over the course of the past 25–30 years, there has been an explosion of public health research and programmes focusing on sexuality. Never before in the history of public health have sex and sexual issues been seen as more worthy of attention. In countries and communities around the world, researchers, practitioners, and policymakers have sought to develop new knowledge, to design new programmes, and to articulate and implement new policies focusing on sexuality and sexual health.

This recent interest in sexuality and public health contrasts significantly with the ways in which sexuality was addressed in earlier times. In the late nineteenth and early twentieth centuries, sexuality was considered at best to be a marginal concern, with attention focused primarily on seeking to control what at the time were called venereal diseases (Brandt 1987). Approaches to such diseases in both medicine and public health were characterized by prevailing moral values of the time, and the primary concern seemed to be with protecting mainstream society from the threat posed by such sexually transmitted diseases.

Over the course of the mid-twentieth century, this situation gradually changed, as growing interest began to focus not so much on sexually transmitted diseases, but on the wider range of what might be thought of as ‘normal’ sexual behaviours of both men and women—less with the goal of protecting them from disease than to seek to promote their health and well-being. This focus reached its zenith in the late 1940s, and the early 1950s with the publication of the Kinsey studies in the United States (Kinsey et al. 1948, 1953). Yet the significant controversy that surrounded the publication of the Kinsey reports, especially in the cold war political climate of the 1950s, quickly led to an almost total curtailment of work on (and financial support for) the topic of sexuality during the ensuing decades (Corrêa et al. 2008).

It was only in the wake of the emerging human immunodeficiency virus (HIV) epidemic in the early 1980s that the consequences of this long-term neglect of public health work focusing on sexuality became apparent. As the devastating proportions of acquired immune deficiency syndrome (AIDS)—a global epidemic transmitted primarily through sexual contact—began to be perceived, the urgent need for greater understanding of sexual behaviour and for innovative new approaches to sexual health promotion quickly became evident. Public health researchers and

practitioners quickly began to seek to address such issues, with a sense of urgency that perhaps could only be generated by such a widespread global crisis, and a new wave of public health research, intervention, and sexual health promotion began and continued to gain strength over the course of the 1990s and the 2000s.

A major aspect of sexuality research has not only focused on a two-dimensional examination of how identities lead to behaviours, but also on the role of desire in grasping the public health implications of sexuality. The collective need to categorize others, as well as the individual need for self-understanding and belonging to a particular community, have created a range of sexual identities throughout the world that are associated with a variety of behaviours and desires. These range from the very Western-centred political identity of being ‘gay’ and ‘out of the closet’, to ‘queer’ identities that proliferated with the development of multicultural societies, to socioeconomically and even caste-related alternative sexualities (e.g. *Hijras* in India), to individual-centred identities defining subcultures within the lesbian, gay, bisexual, transgender, and queer (LGBTQ) framework (e.g. dykes, bois, drama queens). Strategic identities such as that of ‘sex worker’ have in fact empowered some subcultures by reframing categories to diminish the stigma associated to ‘prostitution’. Throughout this chapter we explore some of the implications of this three-dimensional perspective on sexuality (i.e. identity, behaviour, and desire) for heterosexuals as well as non-heterosexuals and among both youth and adults.

This chapter seeks to provide an overview of this rapidly growing body of work in public health. It describes the initial public health response to sexuality in the context of HIV and AIDS, as well as the ways in which the response has been gradually broadened over time in order to provide a more comprehensive approach to sexual health and well-being. It also focuses on both the local and the global dimensions of this work, in both developed and developing countries, and as much in the work of local communities struggling to respond to the needs of their own populations, as well as on the part of a range of international agencies that are increasingly seeking to address a range of challenges to sexual health.

The impact of AIDS

The emergence of the HIV and AIDS epidemic in the early 1980s led to a major transformation in the ways in which public health has addressed issues of sexuality. During the early years of the HIV

epidemic, one of the most frequently repeated laments of public health officials was the lack of data on sexual behaviour and the need to rely on findings from studies, such as the work of Kinsey and his colleagues in the United States, that were nearly 50 years out of date. The urgent need to respond to the epidemic with more contemporary knowledge on sexual behaviour provided the justification for a massive increase in research funding for work on sexuality among diverse population groups, and made the development of public health interventions to reduce the risk of sexual transmission of HIV an urgent priority (Turner et al. 1989).

Driven by epidemiological concerns, research on sexuality in relation to HIV and AIDS was initially developed in medical institutions, and was shaped by Western biomedical assumptions. Much of the early research carried out in response to the epidemic focused on surveys of risk-related sexual behaviours and on the knowledge, attitudes, and practices linked to risk of HIV infection. Most studies collected quantitative data on numbers of sexual partners, specific sexual practices, sexually transmitted infections (STIs), and similar topics related to transmission of HIV. Behavioural research sought to build a scientific foundation for public health policies and intervention programmes that would more effectively prevent HIV infection (Parker et al. 1991).

Very early in the epidemic, however, critical public health and social science research also highlighted the extent to which HIV and AIDS needed to be understood as what Paula Treichler described as ‘an epidemic of signification’ (1988). Such work emphasized the ways in which complex cultural meanings shaped social understandings of the epidemic and surrounded it in deeply rooted forms of stigma, discrimination, and denial (Parker and Aggleton 2003). It highlighted the importance of critically examining epidemiological and biomedical categories as well as popular understandings related to the epidemic, and emphasized the need to investigate local sexual cultures and the social organization of sexual practices in different social and cultural contexts (Parker 2001).

In early work on HIV among gay and bisexual men, for example, it became clear that many men who have sex with other men may not identify themselves as homosexual on the basis of this behaviour, and that Western biomedical categories such as ‘homosexuality’, ‘bisexuality’, or ‘heterosexuality’ might not adequately describe the lived sexual experience of many individuals. Increasingly, descriptive categories such as ‘men who have sex with men’ (or ‘MSM’) were adopted both in research and in public health practice in order to avoid imposing culturally inaccurate or inappropriate labels and classifications. This led, in turn, to important work rethinking the relationship between sexual orientation, sexual identity, and sexual behaviour. Based on this work, it became evident that assumptions about the relationship between sexual desire, sexual behaviour, and sexual identity—in particular, the assumption that feeling desire necessarily led to enacting behaviour, and that enacted behaviour necessarily led to forming a distinct sexual identity based on that behaviour—needed to be re-examined and investigated empirically (Dowsett 2003).

Work on homosexuality and MSM opened the way for a broader critique of other key categories that had been used in seeking to understand the epidemiology of HIV infection. Research on ‘prostitution’, for example, highlighted extensive cross-cultural diversity in the ways in which sex is exchanged for money, gifts, or favours, and emphasized the importance of sex work and sex

workers, on the one hand, and other forms of transaction that might characterize many sexual relationships without constituting sex work or identifying those involved as sex workers or clients (de Zalduondo 1991). Similarly, while the female sexual partners of male injecting drug users (or the male sexual partners of female injecting drug users) might constitute meaningful epidemiological categories, they have little or no sociological significance, and members of groups identified through such categories have little or no sense of self-identity or group identification based on these circumstances, making them largely useless for purposes of health promotion and HIV prevention (Kane and Mason 1992). As a result of HIV and AIDS, then, the ways in which public health has approached issues of sexuality have changed significantly, and a new understanding of sexual health promotion has been developed that has important consequences for other areas of sexual health, independent of HIV and AIDS.

Public health research on marginalized populations such as female sex workers and male and female injecting drug users and their sexual partners also focused growing attention on the broader synergy that exists in many societies between poverty, racial or ethnic discrimination, gender power inequality, and vulnerability to HIV infection (Farmer et al. 1996). It became increasingly clear that sexual behaviour is not somehow isolated or free-floating, separate from other forms of social experience and social structure. On the contrary, sexuality exists embedded in social hierarchies, and sexual behaviour can only be understood within the context of social processes. One of the lasting lessons of the HIV/AIDS epidemic for understanding sexuality in relation to public health more broadly was therefore that sexual risk behaviour must be understood not just as ‘behavioural risk’ but as ‘social risk’—and, indeed, that the concept of ‘risk’ should perhaps be abandoned altogether in favour of a greater emphasis on ‘social vulnerability’ that would be more useful in seeking to understand the social drivers of the epidemic (Parker et al. 2000).

The various insights derived from work on sexuality in the context of HIV and AIDS have continued to shape public health approaches to sexuality over the course of the last two decades. They have been especially important in seeking to develop both research and programmes aimed at promoting sexual health among young people, heterosexual women and men, as well as sexual communities and populations outside the mainstream of society that often face special forms of vulnerability due to emerging forms of social marginalization and exclusion. Work on sexuality in relation to population health has also heightened awareness of the complex ways in which sexual experience is socially regulated, with consequences that can be highly diverse. A broader focus not just on the absence of disease, but on a fuller realization of true health and well-being, in relation to sexuality as in relation to other aspects of health, requires a broader focus on the relationship between sexual health and sexual rights (Parker 2007). Notably, the work of public health has been shaped, through setting a political agenda, cultural framings, and outright displays of indignation with the status quo stemming from AIDS social movements throughout the world (Altman and Buse 2012). The AIDS social movement has been significant in addressing cultural, structural, and social determinants of health not only to increase access to essential medications, but also to give a sense of hope and commitment (a type of sociocultural resiliency) to the study of sexuality in the realm of public health (Parker 2011).

In the following sections of this chapter, we will seek to address the development of work on these various dimensions of sexuality and public health, explore ways in which sexuality intersects with public health issues such as mental health and violence, and to highlight the ways in which this rapidly growing field of work is developing in the early twenty-first century.

Youth, sexuality, and gendered experience

The definition of 'youth' and the timing of a young person's first experience of sexuality are two important considerations for public health researchers and practitioners designing sexual health interventions. The biologically defined developmental stages of youth tend to place an important emphasis on puberty as the beginning stage of human sexuality (Patton and Viner 2007). The onset of puberty brings with it numerous physiological changes and new social pressures for young people transitioning into young adulthood within any given society. Along with adjusting to the new biological changes that are experienced, including the development of secondary sexual characteristics, young people must adjust to the social responses of peers, family, and communities to their obvious physical and emotional sexual maturation. As societies shift from rural to urban, as the advent of formal schooling incorporates greater populations of young people, as influences from globalization and new technologies shape the experience of childhood and young adulthood, and as gender norms continue to evolve, the sexual socialization of young people is being altered and transformed (Blum 2007).

Girls and boys experience puberty differently biologically and socioculturally. Puberty is not only experienced at different ages according to gender, but may be marked by differing rites of passage (broadly defined) that depend on contextual and structural factors. Sexual differentiation moulded by social norms can shape the transformation of gendered expectations and sexual opportunities for girls and boys. The socializing norms influencing young people's development, perceived societal roles, and ultimately their restraint or engagement in sexual risk-taking behaviours are closely linked to the femininity and masculinity norms shaping or constraining their choices and experiences, which we will also address in relation to adult heterosexual relations. In some cultures, girls are de-sexualized at a young age through procedures such as female genital excision, or what has been widely framed by the feminist human rights movement as female genital mutilation (Boyle 2005). Emphasis is generally placed on fertility as the representation of femininity. Boys also undergo sexual rites of passage, but these are often more 'empowering', signifying the acquisition of manhood and emphasizing the importance of virility. Whereas women are sometimes denied sexual pleasure through these procedures, boys that experience male circumcision are ascribed a role in their communities that associates their sexuality with power and responsibility (World Health Organization 2000).

In recent decades, attention has shifted to the social construction of sexuality for understanding the ways in which young people's sexuality and gendered experience are influenced by the societal pressures and traditions around them (Freud 1994). This differentiation based on the social construction of sexuality has concrete implications for gendered disparities in human development related to both education and health. A gendered division of

labour presents significant barriers to closing the gap in illiteracy and access to essential health services in resource-poor settings (Blum and Mmari 2006). In addition, girls are often married-off to older men, and boys are sometimes forced to migrate from rural to urban settings to find work. Both intergenerational sex and migration are factors that contribute to sexual risk.

As young people transition into young adulthood, sexual and reproductive health becomes a priority health issue. This is particularly true for young women in low-income countries, for whom adolescent pregnancy presents particular risks of maternal mortality and morbidity (such as obstetric fistula), infection with HIV and AIDS, and other STIs (Hindin and Fatusi 2009). Adolescent pregnancy makes girls vulnerable to dropping out of school and to mental health problems. Campaigns to prevent STIs and HIV are only beginning to target youth facing structural barriers. The risk of sexual violence is an additional challenge, particularly in societies where gendered power dynamics place young women in positions of little negotiation around sexual relations, and where masculinity norms promote aspects of virility and strength for young men.

Moreover, it is important to question the assumption that sexuality actually begins at puberty. Some studies have shown that sexual experimentation and initiation might begin before this biological landmark (Bankole et al. 2007). Masturbation is a major part of sexual experimentation, and access to pornography on the Internet is widespread. The international community has paid increasing attention to the effects of globalization on trafficking in children and sex work as major public health problems in the contemporary world. This protection of the rights of children is the responsibility of families, communities, and nation-states.

Much of sex education for youth is regulated through kinship networks and schools (Barker 2007). The family and 'traditional values' play an important role in sex education for boys and girls. The age of sexual debut continues to change around the world with influences of modernization and delays in the age of marriage secondary to the advent of formal schooling. The quality of communication between parents and youth influences the ways in which youth are sexually socialized. Religious values that condemn condom use are particularly influential in shaping the types of messages youth receive from their families and in schools. International debates about what constitutes sex education are shaped by progressive advocates for comprehensive approaches (which might include the distribution of condoms to youth for STI and HIV prevention), and by conservatives who believe that sex education should be limited to teaching sexual abstinence until marriage.

More recently, debates over sex education have begun to discuss sexual orientation because at a very young age children begin to experience bullying, especially in schools and on the Internet. School and cyberbullying can lead to increased sexual risk, mental health problems, and substance use among youth. Structural interventions that target school policies are crucial for the formulation and implementation of comprehensive sex education to prevent bullying based on sexuality (Jones et al. 2009).

Heterosexual relations

Public health research on heterosexuality has been relatively limited when compared to the focus on non-heterosexuality. Kinsey's studies began to uncover the gradients of sexuality, as opposed

to a dichotomous divide between heterosexuality and homosexuality—yet, the curiosity for deconstructing the accepted norms was in some ways even aimed at showing the non-existence of an authentic heterosexuality. Historically, the field of sexuality research is laden with bias towards studying ‘deviations’ from the sexual norm rather than at seeking to more fully understand the ways in which dominant normative patterns of experience are produced and organized (Wilkinson and Kitzinger 1994). Paradoxically, daily experience—ranging from the ways sexuality is produced in the media to our interpersonal relations at work, schools, religious institutions, etc.—shows that a notion of heterosexuality exists almost pervasively and that this cultural norm has meaningfully strategic uses in regulating power dynamics in most societies. The concept of ‘heteronormativity’ has been used in critical public health frameworks to describe the ways in which men and women form both casual and steady partnerships, which are moulded by social and cultural norms (Kitzinger 2005). This concept has theoretical traction for understanding patterns of sexual behaviour with important implications for public health outcomes.

The fact that heterosexuality is employed as a form of normative domination at the same time that it has largely escaped the gaze of scientific inquiry calls our attention to how public health can benefit from highlighting recent explorations of heterosexuality. Reproduction, gendered relations of power, masculine/feminine ideologies, marriage, and parenting have more recently begun to be explored at the intersection between sexuality and public health. In large part as a result of the HIV and AIDS epidemic, there has also been growing attention to what can be described as the political economy of heterosexual relationships: the ways in which economic exchange relations shape heterosexual interactions far beyond the context of what is traditionally understood as prostitution or sex work (Hunter 2002). The examination of the transactional nature of heterosexual relations has received special attention in sub-Saharan Africa as a result of research seeking to respond to the need for fuller understanding of vulnerability in relation to the heterosexual transmission of HIV (Leclerc-Madlala 2003; Swidler and Watkins 2007), but is clearly an important, albeit highly variable, part of the organization of partner relations between women and men across widely varying social and cultural contexts that requires increased attention in seeking to develop the field of sexuality in public health more broadly.

Another key area of research that focuses on heterosexual relations has been related to human procreation. According to the World Health Organization, reproductive health relates to having a ‘responsible, satisfying and safe sex life and . . . the capability to reproduce and the freedom to decide if, when and how often to do so’, safely, effectively, and affordably, and through access to health services (World Health Organization 2011a). This discourse comes after decades of public health policies in countries throughout the world, such as those that supported the mass sterilization of women, with a focus on population control as a means to reduce poverty and increase economic growth. These ‘structural’ determinants of health severely limited women’s sexual agency and sexual decision-making.

Moreover, in heterosexual partnerships these asymmetric gendered power dynamics occur not only at a structural level, but they also have effects on individual health outcomes for both

women and men. Ideologies of masculinity have vast implications for public health outcomes globally. Preserving a sense of heterosexual manhood and invincibility has been a barrier to seeking health services (Gough 2013). This has been particularly challenging for public health movements advocating for prostate cancer screening, and heterosexual men are often more averse to anally invasive prostate exams (Gray et al. 2002). The concept of ‘machismo’ or male chauvinism has often been used to analyse the effects of Latin American heterosexual masculinity and its implications for health. Although studies on machismo have associated this ideology with sexual risk behaviours and intimate partner violence, the concept of machismo has been criticized for stereotyping Latino men (Torres 2002). A more complex understanding of Latin American and Latino male sexuality shows that sexual behaviours are dependent on social and interpersonal context. Same-sex socialization among heterosexual men (Kandel and Davies 1991; Ramirez et al. 2012) has been linked to higher levels of sexual risk-taking with women, drug use, and sexual violence.

At the same time, femininity has also been shown to have effects on the health of women. Forms of the ideal ‘sexy’ woman certainly vary across the globe, among cultures, and often depend on social factors such as race and ethnicity. However, there is an overwhelming prevalence of this context-dependent sexualized ideal, which even in its multiform instantiations has impacts on how women perceive themselves. The epidemics of eating disorders are one of the clearest examples of how heteronormative femininity affects women’s health. Public health research has shown that heterosexual women are affected by eating disorders such as anorexia nervosa and bulimia more so than non-heterosexual women (Meyer et al. 2001). Heteronormative femininity is a ‘social determinant’ of women’s sexual health according to the Healthy People 2020’s definition, which lists the factors that limit the ‘availability of resources to meet daily needs, such as educational and job opportunities, living wages, or healthful foods’ (Healthy People 2020 2011), such as violence and discrimination.

Furthermore, heterosexual relations, procreation, and partnerships often result in men and women taking on the responsibility of parenthood. Although parenting is not solely a heteronormative phenomenon in the current world order, public health studies have focused on the negative effects of single motherhood and absent fathers on the sexual and mental well-being of younger generations (East et al. 2007; Ishida 2010). For many, maintaining the institution of *heteronormative* marriage as both religiously and socially stable is a solution to potential health problems associated with heterosexual relations (Mahoney et al. 2008). However, the more critical public health research has associated ideologies with heteronormative marriage with infidelity, intimate partner violence, and sexual risk (Hirsch et al. 2007).

The purpose of this section was to highlight the absence of a necessary critique of heterosexual relations by considering political, economic, cultural, social, and interpersonal determinants of health. Both methodologically and analytically, heterosexuality has mostly been treated as the ‘referent’ category in public health work on sexuality. Our critique is not of heterosexuality in itself, but of the multiple forms of inequalities that result from male dominant power relations that are overall unfavourable for women and men.

Sexual diversity and alternative sexualities

Framing sexual diversity in public health is methodologically and epistemologically complicated, particularly because of how sexual desires, behaviours, and identities converge and diverge. Addressing sexual *identities* might be easier in social and behavioural research because there is more reliability in measures when the respondent identifies either to themselves or openly to society about being a LGBTQ individual. Alternative sexualities go beyond identity, however, and a person who practises same-sex sexual behaviours or sex work might not identify with a particular group culture. It becomes even more complicated when speaking of desire that does not necessarily translate into behaviour or identity formation, as we mentioned earlier. Research questions vary depending on these dimensions of sexual diversity and alternative sexualities, and public health has often collaborated closely with social movements to set research agendas.

The broader framework of sexual health has been employed to study health problems related to populations characterized by sexual diversity (Parker et al. 2004). Much of public health research has focused on behaviour change towards the practice of safer sex (e.g. through condom use and reduction in sexual partners), especially considering the disproportionately high impact of HIV and AIDS on gay and bisexual communities (Cow et al. 2011; Millett et al. 2012). Scholars have also focused on the intersections of mental and sexual health. Using theories such as ‘minority stress’ scholars have focused on distal and proximal factors that affect depression, anxiety, and healthcare utilization (Meyer 2003). Fear of disclosure of having same-sex desires or of practising alternative sexualities, for instance, can have important implications on the ways people interact with their healthcare providers (Klitzman and Greenberg 2002). Sexual diversity interacts with other social factors, such as race and poverty, which lead to differential access to healthcare and exposure to disease (Díaz et al. 2001).

In the sexual health literature, there have been disputes over how to create epidemiological categories that capture sexual diversity. The categories men who have sex with men (MSM), men who have sex with men and women (MSMW), and women who have sex with women (WSW), behaviourally bisexual, bisexual, gay, and non-heterosexual are all used in the field of public health depending on the research question involved. Some of these categories, such as MSM, attempt to capture self-identified gays and bisexuals as well as those who practise same-sex sexualities but that do not self-identify as gay or bisexual. The category MSM might strip away the social and political implications of public health work on alternative sexualities, which has been a prominent claim among public health activists. Categorizing populations such as MSM and WSW might be understood as an attempt to objectively perform science. Those advocating for LGBTQ health are part of a public health social movement that contends that understanding non-heterosexuality as having vast variation in sexual performance is central to a notion of well-being that hinges on social rights. The epidemiological use of categories such as MSM and WSW, among others, does not fully take into consideration that ‘community, networks, and relationships in which same-gender pairings mean more than merely sexual behavior’, and these categories have been criticized by the public social movement as heterosexist (Young and Meyer 2005). Another trend in public health

that has been disputed is having sex on the ‘down low’ (Millett et al. 2005). Sex on the down low describes patterns of secrecy and discretion that facilitate extra-marital sex, keeping a heterosexual identity while having same-sex sexual relations, and sexual concurrency.

There has been less attention to the particular health disparities that affect lesbians and women who have sex with women in the public health literature (Bauer and Jairam 2008). This gap is probably due to the lesser impact that HIV and AIDS has had on these populations, when compared to other ‘risk’ groups. This has led to gaps in research for women who are vulnerable to HIV, although other STIs such as HPV (which causes cervical cancer in women) have been addressed in non-heterosexual women populations (Charlton et al. 2011). Bisexual women and women who have sex with women and men (WSWM) have had some attention particularly regarding their sexual health. There are important concerns about the unmet needs of lesbians, bisexual women, and WSWM in healthcare due to stigma and discrimination when seeking health (Stevens et al. 1988). This is especially the case when they fear disclosing their sexualities. Lesbians and bisexuals have been identified as having a higher rate of cigarette smoking than heterosexuals in national studies (Ryan et al. 2001). The health concerns of lesbians are more proximal to those of heterosexual women (relative to comparing gay men with heterosexual men). However, non-heterosexual women encounter barriers in sexual and reproductive health, as well as in making important life decisions, such as child-bearing that make them particularly vulnerable to stigma and discrimination (Dahl et al. 2013).

The mental and physical health of transgender men and women has drawn special attention in public health, especially in discussions about gender modification procedures, the formal classification of transgender individuals in the *Diagnostic and Statistical Manual of Mental Disorders*, and their access to health more generally (Lombardi 2001; De Cuypere et al. 2010). Illegal hormone and silicone injection has been of particular concern due to the high cost of gender transformation (Wiessing et al. 1999). Moreover, stigma and discrimination are probably most prevalent for transgender individuals, limiting their employment and education opportunities. These are social aspects of their gender identities that directly affect their risk for HIV and AIDS and mental health problems, especially because many transgender women resort to commercial sex work because of their limited opportunities (Abdullah et al. 2012). In some countries, such as Brazil and Cuba, public health policy debates about government funding for gender modification are being couched in human rights frameworks and public health safety (Gorry 2010).

Moreover, male and female sex workers are among the most vulnerable populations for HIV infection, sexual violence, and drug use (Mayhew et al. 2009). The public health implications of sex work (and the shift to applying a human rights framework) have been explored through a variety of methods, including qualitative and ethnographic techniques. Innovative public health research and interventions have studied sexual risk and mental health risks throughout the world (Kempadoo 2003). Sex work, intergenerational sex, and gift-exchange for sex have been documented throughout the world, and it has been linked to factors such as food insecurity (Weiser et al. 2007). Progressive public health has shown that sex workers can no longer be thought to be merely victims, but have come to take on the role of the human

rights advocates throughout the world pointing to the elements of structural stigma and discrimination that led to their condition.

It is a challenge to study sexual desire and behaviour in populations where assuming an identity puts the person at sociocultural, political economic, and even legal disadvantages. Because of the stigma and discrimination associated with non-heterosexual sexualities, non-politicized alternative sexual communities and/or individuals are often 'hidden' or hard to reach. Such populations have a number of distinctive characteristics, including the fact that no sampling frame exists for them because their boundaries and their size are unclear or unknown. Perhaps even more importantly, members of these populations may often be unwilling to cooperate with research activities or public health programmes because of their understandable fear of experiencing stigma and discrimination as a result of their participation. Widely used research methods, such as household or neighbourhood surveys, are therefore ineffective (as well as inefficient because of the fact that the number of persons in such hidden populations is typically relatively small) (Ramirez-Valles et al. 2005).

Public health studies and interventions on hidden populations are among the most methodologically innovative. Snowball sampling or chain-referral sampling are common techniques in achieving a theoretically defined number of participants in qualitative research in fields such as anthropology and sociology. Respondent-driven sampling is a type of chain-referral sampling in which study participants refer others to the study, beginning with key informants or seeds that can be randomly selected. This form of chain-referral provides a dual incentive for the participant and weights the sample. Respondent-driven sampling lends itself to social network analysis if referral systems and patterns are tracked. In fact, this can be particularly useful in public health to study sexual networks, networks of drug users, or sex workers (Ramirez-Valles et al. 2005). More researchers are beginning to bridge the gap between qualitative and quantitative approaches, as well as forging interdisciplinary perspectives, precisely because they acknowledge the complexities of studying sexual diversity in public health. It is now more common for studies with large probability samples to explore multilevel research questions that require a complementary approach of ethnography and survey methods.

Social regulation of sexuality

The social regulation of sexuality impacts how public health studies are conceptualized, designed, and executed. A range of formal and informal institutions and community structures define socially accepted expressions of sexuality, delineating cultural and social psychological norms. Social regulation might occur to enforce moral 'tradition', especially when relating sexuality with heteronormative reproductive practices.

Legal frameworks are regulations with implications on sexual practices as well as on gender roles. Throughout the world, laws determine the ways in which sexuality affects economic and political issues, such as through the institution of marriage, which marginalizes non-heterosexuals. Laws that ban sodomy or that deny adoption privileges based on sexual orientation target non-heterosexuals and punish the unmarried. Legal systems also dictate who has control over the female body, what women are allowed to wear, how women are inherited through generations

of men in some countries, the kinds of sexual pleasure women should be granted, and in some cases laws sanction gender-based violence.

Social networks might regulate sexuality through 'soft' mechanisms such as gossip or 'harder' mechanisms such as ostracism from communities if non-conforming sexualities or gender roles are expressed. Families and schools are among the most important institutions in directly providing sex education for children and adults throughout the world. While families are often thought of as spaces for social support, conservative family values that condemn homosexuality, for example, might create structural vulnerabilities to mental health problems, including depression, substance use, and thoughts of suicide among LGBTQ youth. Schools and their political agendas on sexuality vary, having a major impact on the sexual formation of the individual and her/his interaction with peers. Policy interventions, such as those that ban bullying in schools, might have vast implications for public health outcomes.

Community-based groups and civil society organization such as faith-based organization have varied on their position on sexuality and public health. Some religious traditions, such as Pentecostal evangelicals—which have been proliferating in numbers throughout the world in the twentieth and twenty-first centuries, have been the most adamant proponents of public health campaigns that promote the reduction of sex partners, faithful relationships, and waiting until marriage, among other more conservative approaches to regulating sexuality at the expense of excluding non-heterosexuals and gender non-conforming individuals from their messages and flocks. In research on Afro-descendent religions in countries such as Brazil, some faith-based organizations have been shown to embrace alternative sexualities and sexual diversity, as well as have a strong platform for women's equality and rights (Garcia and Parker 2011).

Also noteworthy, the Internet is among the most influential social/virtual institutions in contemporary life that shape and regulate sexuality and sexual norms. The pornography industry is ever growing and few public health studies have systematically analysed the association between exposure to pornography and sexual behaviour, some finding that increased exposure to pornography is associated with higher sexual risk-taking (Eaton et al. 2012). Social networks and smartphone applications (apps) such as Grindr (which uses advanced GPS systems to locate proximal partners in the vicinity of the individual essentially to meet up and have sex) are often used to meet new sexual partners and fulfil sexual fantasies that were once only imagined. Even though the Internet has been more liberating than limiting in its forms of social regulation, conservative civil society groups are ever present on the worldwide web with moralizing, normalizing, and moderating tendencies that often make people afraid of having excessive sexual pleasure.

The public health implications of the social regulation of sexuality are extensive. Regulatory groups and mechanisms include not only legal frameworks, but also the family, schools, religious groups/institutions, formal community leadership structures, informal structures that generate social (and virtual) capital, just to name a few, which have been considered important in public health studies and interventions related to sexuality. When considering the possibility of targeting sexual behaviours through community and ecological interventions and studies, we call

for new methodologies that analyse both heterosexual and non-heterosexual practices and pleasures. For example, cellular phone technologies and innovative forms of ethnographic mapping that examine trends on how virtual social networks on the Internet could contribute to a greater understanding of how sexual desires are enacted. These technologies can also be used to target vulnerable populations that might be excluded from participation in civil society organizations through self-selection or through social sanctioning.

Sexual health and sexual rights

The notion of sexual rights is the counterpart to social regulation. The emphasis on sexual rights has helped to constitute a fairly new field of public health and this framework draws on interdisciplinary and intersectoral approaches to improving collective health outcomes in what can be considered a public health social movement. Even though international mobilization has dominated the use of the term 'sexual rights' as a rallying framework in global activism, sexual rights are often only regulated effectively as they are interpreted and understood on the local level in families, at schoolyards, by community-based groups and non-governmental organizations (Garcia and Parker 2006).

The language of sexual rights in public health stems greatly from the application of a human rights framework to addressing not only individual, but also social and structural vulnerabilities. Human rights are generally understood as universal and fundamental rights deserved equally by all people. The International Conference on Population and Development (ICPD) held in Cairo in 1994 was a watershed moment for the transnational dissemination of discourses of sexual rights, although the official document of the ICPD did not include in it a clear mention of the term 'sexual rights' after much heated debate among conservatives and progressives (Petchesky 2000).

Although public health leaders have partnered with activists throughout the world to push for sexual equality to be considered part of our fundamental rights, it has been difficult to include sexual rights as part of framing documents at the level of the United Nations because of their contentious nature. International discourses about reproductive and sexual rights have been rooted primarily in Western individualism, even though notions of bodily integrity and personhood have a long history in non-Western contexts, in which they are more intertwined with social and cultural norms and collective rights (Corrêa and Petchesky 1994). To address vulnerabilities that are contingent on context, culture, and structures, it is paramount to include access to resources and the community-level conditions that might enable or restrict sexuality and health.

Moreover, sexual rights emerged under the umbrella of reproductive rights (which focused primarily on gender inequality, violence against women, and population control, among other heterocentric issues), but health rights activists and LGBTQ groups have pushed the envelope to develop a concept that goes beyond human reproduction and addresses non-heterosexual health and rights-based issues (Miller 2000). Although sexual health is often confounded with reproductive health, there has been an attempt to differentiate the two by the World Health Organization. These include the right of all persons, free of coercion, discrimination and violence, to: 'a state of physical, mental and social well-being

in relation to sexuality. It requires a positive and respectful approach to sexuality and sexual relationships, as well as the possibility of having pleasurable and safe sexual experiences' (World Health Organization 2011b).

While sexuality can include all of these dimensions, not all of them are always experienced or expressed. The 'responsible' exercise of human rights requires that all persons respect the rights of others. Within the framework elaborated by WHO, sexual and reproductive health are central aspects of life at all ages and encompass sex, gender identities and roles, sexual orientation, pleasure, and reproduction. Sexuality is experienced and expressed in thoughts, fantasies, desires, beliefs, attitudes, values, behaviours, practices, roles, and relationships. Sexuality-related vulnerabilities highlight why these issues ought to be framed as inextricably tied to other human rights, political and civil liberties, and economic rights.

The protection from harm, be it for heterosexual or non-heterosexual populations, has been the main focus of the sexual rights movement. Nonetheless, sexual pleasure has also been conceptualized as an integral part of sexual rights by activists and also by progressive public health campaigns. One example of harnessing the power of the sensual in social marketing is the eroticization of the condom. Rather than showing the condom in isolation as a prophylactic barrier to natural sex, campaigns throughout the world have used sex symbols to entice safer sex—almost as a form of harm reduction in which people are assumed to be having sex in any case, so these campaigns make 'safer', sexy. Sexual rights frameworks that are emerging throughout the world are giving birth to new debates about gender and sexual equality that goes beyond reproduction (not to downplay the utmost importance of debates about new reproductive technologies that are more inclusive of non-heterosexuals).

Conclusion

Especially during the closing decades of the twentieth century and the beginning of the twenty-first, the field of sexuality and public health has taken shape as one of the fastest growing areas of research and intervention in relation to population health. It is a field that has been characterized historically as highly polemical, often marked by controversy and disagreement based on conflicts in relation to fundamental values and ethical positions. But at least since the emergence of the HIV/AIDS epidemic in the early 1980s, we have also realized that ignoring issues of sexuality, sweeping them under the carpet or leaving them hidden away in the closet, does nothing to promote the realization of true sexual health and well-being. This is especially worrisome when sexual norms, as we have pointed out, lead to grave disparities in health. On the contrary, it is only by bringing sexuality out into the open, by freeing it of stigma, prejudice, and discrimination, and by building a culture of sexual rights, freedoms, and protections, that we can truly advance the cause of sexual health and well-being. In this sense, it is clear that public health work on sexuality in the early twenty-first century both grows out of and is aligned with the long tradition of public health as a social movement—a movement based on principles of social justice and human rights, capable of promoting health for all based on a foundational set of ethical and political principles. Far from a peripheral concern related to a taboo topic, few areas of work are so central to a public health project for the present.

Demography and public health

Emily Grundy and Michael Murphy

Introduction to demography and public health

The health and healthcare needs of a population cannot be measured or met without knowledge of its size and characteristics. Demography is concerned with this and with understanding population dynamics—how populations change in response to the interplay between fertility, mortality, and migration. This understanding is a prerequisite for making the forecasts about future population size and structure which should underpin healthcare planning. Such analyses necessitate a review of the past. The number of very old people in a population, for example, depends on the number of births eight or nine decades earlier and risks of death at successive ages throughout the intervening period. The *proportion* of very old people depends partly on this numerator but more importantly on the denominator, the size of the population as a whole. The number of births in a population depends on current patterns of family building, and also on the number of women ‘at risk’ of reproduction—itself a function of past trends in fertility and mortality. Similarly, the number and causes of deaths are strongly influenced by age structure.

Demography is largely concerned with answering questions about *how* populations change and their measurement. The broader field of population studies embraces questions of *why* these changes occur, and with what consequences.

This chapter presents information on demographic methods and data sources and their application to health and population issues, together with information on demographic trends and their implications and the major theories about demographic change, in order to elucidate the complex interrelationship between population change and human health.

Global issues

Fig. 6.3.1 shows that the world’s population has recently been growing at an unprecedented rate and was estimated to be 7.05 billion at mid 2012 (UN 2011). While it took an estimated 123 years (from 1804 to 1927) for the world to increase its population from 1 to 2 billion, the increase from 6 to 7 billion was achieved in a tenth of the time (1999–2011). The United Nations (UN’s) medium projection suggests a further increase of some 2.3 billion by 2050 (UN 2011). Beyond this, there is a good chance that global population growth will cease by the end of the twenty-first century (Lutz and Samir 2010).

This prospect of global population stability masks huge differences between regions and between richer and poorer countries. Between 1950 and 2000, 77 per cent of world population growth occurred in countries currently designated by the UN as less developed (excluding the least developed, see Box 6.3.1 for definitions); 13 per cent in least developed countries and 11 per cent in more developed regions. Between 2000 and 2050, medium-term projections suggest that population growth in more developed regions will account for only 4 per cent of the total with 63 per cent occurring in less developed countries and 33 per cent in the least developed countries. These projections imply that by 2050 the share of the world’s population living in currently more developed regions will account for only 14 per cent of the total world population—compared with 32 per cent a century earlier—while the representation of those in the poorest countries will have increased from 8 per cent of the total in 1950 to 19 per cent in 2050.

These hugely differing rates of growth arise from differences in vital rates, and associated large variations in age structures, which are illustrated for regions and selected countries within them in Table 6.3.1. In a number of European countries and some Asian

Fig. 6.3.1 Population and projected population of the world and more, less, and least developed regions, 1950–2050.

Box 6.3.1 Country and regional classifications by level of development

The UN classifies countries into ‘more’ and ‘less’ developed and also identifies a group of 50 ‘least developed’ countries. The more developed category includes all of Europe, North America, Australia, New Zealand, and Japan. The least developed countries are mostly in sub-Saharan Africa but also include Afghanistan, Bangladesh, Cambodia, and Myanmar. The classification has some anomalies in that some wealthy Asian and Near Eastern countries are counted as less developed (e.g. South Korea, Singapore, Cyprus, Israel) whereas some poorer former Eastern bloc countries are treated as more developed (e.g. Albania, Belarus, Bulgaria).

The World Bank employs a classification based on gross national income per capita which divides countries into high-, middle-, and low-income groups, with a subdivision of the middle into upper and lower. Some of the countries (principally from Eastern Europe) classified by the UN as developed fall into middle-income categories, while some of the UN less developed group are classified by the World Bank as middle income (principally Latin American) or high income (some South East Asian).

Membership of the Organisation for Economic Cooperation and Development (OECD) is also sometimes used as an indicator of developed country status; members include Russia and Mexico, both of which are classified by the World Bank as middle- rather than high-income countries.

The Human Development Index compiled by the UN Development Programme takes into account factors other than income, such as school enrolment, literacy, and levels of mortality.

Regional groupings employed by different international agencies also vary slightly. Further details of all these classifications are available on the relevant organizations’ websites.

While some regions grapple with the needs of rapidly growing populations, such as large increases in requirements for child health services and schools, others face challenges of population ageing and, in some cases, population decline. By 2025, nearly a quarter of the Western European population is expected to be aged 65 or more and in some countries, such as Japan, South Korea, Spain, and Italy, projections suggest that a third or more of the population will be aged 65 and over by 2050 (UN 2011).

Table 6.3.1 Indicators of age structure, fertility, and mortality: world regions and selected countries, 2011

Region/country		Proportion (%) of population aged:		Total fertility rate	Life expectancy at birth (years)
		<15	65 and over		
Africa		41	3	4.6	58
	Sub-Saharan	43	3	5.0	56
	Northern	33	5	3.1	70
Asia		25	7	2.2	70
	India	30	5	2.6	67
	China	18	9	1.5	75
	Japan	14	23	1.4	84
	Indonesia	27	6	2.3	71

Fig. 6.3.2 Cumulative distribution of deaths by age; Sierra Leone 2009, Egypt 2009, Chile 2008, Japan 2009.

Source: data from United Nations Department of Economic and Social Affairs, Demographic Yearbook 2011, ST/ESA/STAT/SER.R/41, United Nations, New York, USA, Copyright © United Nations 2012, available from <http://unstats.un.org/unsd/demographic/products/dyb/dysets/2011.pdf>

countries, such as Japan, women on average have only 1.4 children or fewer (see Box 6.3.2 for derivation of total fertility rate), and people aged 65 and over outnumber children under 15. In sub-Saharan Africa, women on average have five children each, 40 per cent or more of the population is aged 15 or under, and only 3 per cent aged 65 or more.

Levels of mortality, and associated differences in age and cause distribution of death, also vary markedly. In some high-income countries, average life expectancy at birth is above 80, while in some sub-Saharan countries it is below 50, substantially because of HIV/AIDS. As shown in Fig. 6.3.2, in Sierra Leone, 40 per cent of all deaths in a year are of infants and children aged under 5, compared with 0.3 per cent in Japan. Conversely, of all deaths, 70 per cent in Japan and 50 per cent in Chile, a middle-income country, are of people aged 75 and over; equivalent proportions for Egypt and Sierra Leone are

20 per cent and 8 per cent respectively. These variations have enormous implications for health and healthcare priorities in, and beyond, the populations concerned. Divergence in population growth between regions of the world is also fuelling mass migration, which itself has implications for global population health (Fernandes et al. 2007).

Closely related to variations in the distribution of deaths by age are differences in the cause structure of death. As shown in Table 6.3.2, communicable diseases, maternal and perinatal conditions, and nutritional deficiencies account for 67 per cent of all deaths in sub-Saharan Africa but only 5 per cent in Europe. Conversely, non-communicable diseases are responsible for 25 per cent of deaths in sub-Saharan Africa, 66 per cent in Asia, but 88 per cent in Europe. While in parts of the world, communicable diseases and reproductive and child health present the most pressing public health problems, concerns about the prevalence

Table 6.3.2 Distribution of deaths (%) by cause group and world region, 2010

	Communicable	Non-communicable	Injuries
Global	24.9	65.5	9.6
Europe	5.1	88.3	6.6

of age-related chronic degenerative diseases predominate in others. In sub-Saharan Africa, 1.2 million deaths are due to HIV/AIDS. Although the numbers of such deaths are estimated to have peaked globally around 2005 (UNAIDS 2012), they still represent a substantial and long-term burden (UN 2011).

The process that separates populations with high fertility, relatively high mortality, young age structures, and rapid growth from those with low vital rates, older age structures, and slow or no growth, is conceptualized as the demographic transition. Identifying, and explaining, this and associated profound changes in health has been a central preoccupation of modern demography (Lee 2003). Before turning to these issues, the basic methods and materials of demographic analysis must be considered and the issue of population dynamics—*how* populations change—addressed.

Demographic data and methods of analysis

In the seventeenth century, John Graunt, a London merchant, used data from the London Bills of Mortality to devise an early life table, leading to him being dubbed the ‘father of modern demography’. However, while Graunt had information on *numbers* of deaths, he lacked data on the population at risk and could not compute death *rates*. Essentially all demographic analysis requires data both on the population ‘stock’ and on ‘flows’ in and out—births, deaths, and migration. The traditional sources of information on the former are population censuses and, for the latter, vital registration systems.

Population censuses

The first ‘modern’ censuses were undertaken in Scandinavia in the eighteenth century. Censuses spread throughout Europe during the nineteenth century and most of the rest of the world in the twentieth. As well as basic questions about age, sex, marital status, and place of residence, data on other characteristics such as employment, education and housing are often collected. The UN recommends that censuses be conducted at least decennially in years ending in 0 or 1.

Censuses have many strengths and are often the only source of data for small areas or population subgroups. Although primarily a tool for collecting data on population ‘stock’, censuses have also been used to find out about vital events. Many countries use censuses to provide data on recent internal migration (through questions on place of residence 1 or more years earlier) and immigration (through questions on country of birth and/or date of entry for those born elsewhere). Indirect estimation techniques developed by Brass and others mean that questions on number of children born and number who have died, on widowhood, and orphanhood are widely used to assess mortality levels and trends using both censuses and surveys in countries with deficient vital registration systems (Preston et al. 2001).

However, censuses involve huge costs and the challenge of ensuring acceptable data quality. Approaches to reducing cost (and improving quality) include use of sample censuses, either for the census as a whole, as in China, or for more detailed questions, as in the United States. Census taking requires not only a reasonable administrative infrastructure, but also the

cooperation of the population to be enumerated. Some countries have given up taking censuses because the latter is lacking and now rely on large-scale surveys or ‘virtual censuses’ based on population registration data. The twenty-first century is seeing more countries adopting alternatives as the information required by governments becomes more complex and the difficulties of mass data collection escalate. In 2010, only 11 of the 27 current European Union members conducted traditional censuses (Valente 2010).

When censuses are taken, difficulties arising from errors and omissions are common, even in countries with a long history of census taking. Young, geographically mobile adults, recent (especially unauthorized) immigrants, members of minority ethnic groups, infants, and the very old are those most likely to be under-enumerated—some of the very groups that policymakers and health professionals may be most keen to know about.

Groups such as seasonal migrants, military personnel, people temporarily away from home, and those with more than one residence also present problems. Not only are they more likely to be missed, but a decision has to be made about whether they should be assigned to their place of usual or legal residence (assuming it can be determined), or counted as belonging to the place of enumeration. The former system is termed *de jure*, the latter *de facto*. The issue of assigning people to some place of usual residence is important as often resources are allocated based on population size and characteristics. Moreover, it is essential to try and ensure that demographic events recorded in one system (vital registration) are attributed to the population actually ‘at risk’ of experiencing them. In richer countries, for example, most deaths occur in hospitals which may draw patients from a wide area. If these decedents are not assigned to the locality where they lived prior to hospital admission, areas including large hospitals will appear to have very high mortality rates while in others, recorded mortality will be artificially low.

Under-enumeration is usually assessed through census validation surveys (surveys of a sample of census addresses in which intensive efforts are made to contact non-respondents and check information supplied by respondents) and comparisons with population estimates from other sources. Beyond ensuring near-complete enumeration, the quality of the data collected is also a major concern.

In many populations, people may not always know their exact age and some approximation is reported or made by an enumerator. ‘Heaping’ on ages ending in 0 or 5 is a common result. Heaping can be detected by looking at the age distribution and applying various tests of consistency and such data are normally adjusted before publication. More serious problems arise when reported age is based on other characteristics, such as marital status, number of children or grandparent status, as clearly any analysis of, for example, age at first marriage, will be biased if people’s report of their age is influenced by their marital status.

Vital registration

Data on demographic events, as well as on population characteristics, are needed. In richer countries these are drawn from vital registration. Compulsory registration of births and deaths was established in most European countries during the nineteenth century. In England and Wales, for example, civil registration

was introduced in 1837. Subsequent improvements to the system included those following the 1874 *Births and Deaths Registration Act* which made parents legally responsible for registering births and required attending physicians to supply information on cause of death. Other revisions have since been made, for example, the inclusion of first mother's and later father's age and in 2012, recording of all children previously born, rather than just legitimate ones, on the confidential section of birth certificates. Most high-income countries have well-established registration systems with complete, or very near complete, coverage. In poorer parts of the world, however, vital registration systems are frequently seriously incomplete or non-existent, although there are exceptions and some countries, including India and China, have sample registration systems for selected areas. Currently only about a third of deaths estimated to occur globally are registered and reported to the World Health Organization, although if the sample registration systems in India and China are considered as sufficiently representative of their national populations, this proportion rises to 72 per cent (Mathers et al. 2005).

The quality of the information supplied and coded is of course very important. No one registers their own death and the information obtained from proxy informants may be inaccurate. Differential reporting of age, occupation, marital status, or other characteristics in the census and in other sources, such as death certificates, presents a further difficulty. Numerator–denominator discrepancies may introduce serious bias into the analysis of mortality at advanced ages, or by characteristics such as occupationally defined social class, marital status, or ethnicity (Williams et al. 2006). The Nordic and some other European countries avoid these problems by maintaining well-developed register-based systems that link vital registration data to population, occupational, and educational registers. One study of marital status differences in mortality at older ages found marked differences in results for countries using traditional and register-based systems (Murphy et al. 2007).

Cause of death

Death certificates are the major source of information on cause of death. In richer countries, cause of death is generally certified by a physician and coded according to the International Classification of Diseases (ICD) which originated from work undertaken by the nineteenth-century British medical statistician, William Farr. The tenth revision of the ICD came into use from 1994 and included nearly twice as many codes as ICD-9. ICD-11 is in preparation and is expected to come into use in 2015. National preferences, as well as ICD revisions, may influence assignment of cause of death, as illustrated in a number of classic papers in which case studies of deaths were distributed to physicians in different countries. Growing awareness of particular conditions may also influence coding practices. In the United States, Australia, and elsewhere, for example, there have been large increases in mentions of Alzheimer's disease and other dementias on death certificates since 2000. These partly reflect some changes associated with the introduction of ICD-10 but also effects of increased awareness and some specific campaigns to increase recognition of these conditions (Moschetti et al. 2012).

Older people, now the vast majority of decedents in low-mortality populations, are more likely to suffer multiple pathologies and the number of conditions recorded on death certificates has been

increasing. Choice of one over another as the 'true' underlying cause of death is bound to be partially arbitrary. In the United Kingdom, for example, between 1984 and 1992 some 25 per cent fewer deaths were allocated to respiratory diseases purely as a result of changes in the rules used to select underlying cause of death (Griffiths and Brock 2003). Multiple coding of death certificates and analyses by all mentions of a condition may be more informative but such data are available in only a few countries (Anderson 2011). Variations in death certificate coding reflecting differences in medical knowledge and diagnosis, in the extent to which autopsies are used, in classification systems, and the quality of registration systems are a major factor complicating analyses of trends over time or between countries.

Deaths assigned to symptoms, signs and ill-defined conditions such as 'old age' or 'senility' or other causes lacking diagnostic meaning, sometimes referred to as 'garbage codes', present a particular problem. Mathers et al. (2005) in an investigation of coverage and quality of cause of death coding in 2003, found that in some countries over 40 per cent of deaths were assigned to these 'causes'. Only 23 countries met their definition of high quality of data with coverage of at least 90 per cent and fewer than 10 per cent of deaths assigned to ill-defined codes.

Variations in coding practices and use of ill-defined codes complicate comparisons over time, as well as between countries. Preston (1976) argued that there was an inverse association between the proportions of deaths assigned to circulatory diseases and to ill-defined causes, and that part of the apparent twentieth-century epidemic in heart disease mortality in richer countries may have been an artefactual consequence of improvements in death certification. A review of the proportion of all deaths in England and Wales assigned to circulatory diseases and to ill-defined causes in age groups over 65 from 1911–1915 to 2001–2010 is instructive. Early in the twentieth century, large proportions of deaths among the very old were assigned to ill-defined categories and declines in this proportion were associated with increases in the proportion attributed to circulatory diseases. The proportion of ill-defined deaths in the oldest group aged 80 and over was, however, slightly higher in 2001–2010 than in the preceding period, reflecting increased assignment to 'old age' as a cause. Reasons for this are unclear, although the cessation in 1993 of further enquiry into vague causes of death may have been a small contributory factor. Use of this 'cause of death' is likely to be reversed again in response to the 2000–2005 public enquiry into the case of Harold Shipman, a British family doctor whose serial murder of over 250 elderly patients was not detected for many years; an illustration of the importance of surveillance of deaths for reasons other than epidemiological or demographic investigation.

In countries which lack adequate certification and registration systems, data on deaths by cause are seriously limited. Attempts have been made to develop verbal autopsies, protocols for collecting information from lay informants which can be reviewed by physicians and used to assign cause of death (Wang et al. 2007). This approach has been useful in a number of small investigations and is being employed on a larger scale, for example, in India (Gajalakshmi and Peto 2011). However, a recent study tested physician-certified verbal autopsies in six sites in four poorer countries against gold standard assessment and found a concordance of less than 50 per cent, with substantial variability by cause and physician (Lozano et al. 2011). In the absence of

routinely recorded data, estimates may be obtained by modelling. This has been used for the important issue of establishing the number of deaths from HIV/AIDS. The most ambitious exercise is the Global Burden of Disease programme which has used a large array of sources and methods, including expert knowledge, vital registration, field surveys, surveillance, and police and mortuary data to derive estimates of cause-specific mortality by age and sex for 235 separate causes for every country in the World (Wang et al. 2012).

Other data sources

Many countries have a range of surveys which provide more detailed information on, for example, health-related behaviour, family building strategies, reasons for migration, or information on biomarkers that would be impossible to collect in a census. In poorer countries, where other data sources are scarcer, surveys often present the best source of data on basic demographic parameters. Data quality is potentially better in a survey than a census, as it is more likely that well-trained interviewers can be used. The World Fertility Survey (WFS), an international population research programme launched in 1972 to determine fertility levels throughout the world, and its successor, the Demographic and Health Survey Programme (DHS), have been particularly valuable in providing demographic and health data for a range of poorer countries. Other approaches include multi-round surveys, in which respondents are asked about events since last contact, and dual-record systems which involve two independent data collection systems (one often a multi-round survey), the results of which are then combined. This method allows some estimation of missed events, but is expensive. These approaches are described in more detail in most demographic textbooks (Preston et al. 2001; Rowland 2003; Siegel and Swanson 2004).

The raw materials of demography relate to individuals' most personal experiences—sexual activity, family formation, birth control, reproduction, marital breakdown, illness, and death. All of these occur in a social framework which attaches value to some of these behaviours and stigmatizes others. Not surprisingly, respondents in censuses and surveys may be reluctant to disclose non-marital pregnancies, illegal abortions, undocumented migration, or deaths of relatives from AIDS. Concealment has also been the policy of some national governments which have treated demographic data as official secrets. Additionally, the enormous potential complications arising from people's uncertainties about age or other 'basic' characteristics including children ever-born; uncertain recollections of prior events and the vast scope for administrative errors have to be considered. The demographer's traditional obsession with data quality is hence understandable. Differences in perceptions and reporting of health status are also problematic and have bedevilled attempts to make international comparisons of health status as, even if questions are harmonized, the ways people respond to them are not (Ritu et al. 2002).

The statistics produced in series like the *United Nations Demographic Yearbooks* have their origins in what is or has been done by millions of people, mediated by what is said about these events and experiences, further filtered by how this is recorded, processed and analysed. Some assessment of data quality is given in the *United Nations Demographic Yearbooks*, but sometimes users may pay insufficient attention to this. A number of other organizations also produce international reference works and

databases including the World Health Organization (WHO), the World Bank, the Organisation for Economic Cooperation and Development (OECD), Eurostat, The United States Census Bureau International Data Base (United States Census Bureau n.d.), and the Human Mortality Database. In most cases, these are available free of charge online.

The analysis of demographic data

A standard array of techniques and measures forms the basis of much demographic analysis; the most common of these are described briefly here. Further detail is supplied in a number of textbooks (Preston et al. 2001; Rowland 2003; Siegel and Swanson 2004). Analysis involves not just the application of a particular technique, but also decisions about what units of analysis to use and how to group them. A major distinction is between *period* and *cohort* analysis. Period analysis deals with events of a particular time period (e.g. mortality rates from 2005 to 2010) while cohort analyses follow the experience of individuals through time. Cohorts in this sense are defined as groups of people who have experienced the same significant event at the same time. Thus birth cohorts comprise people born in a particular year or group of years and marriage cohorts those marrying at a particular time. Cohort and life-course approaches to analysing mortality and other indicators of population health have an intuitive appeal and are increasingly used, both fuelling and fuelled by a growing number of longitudinal studies. Cohort analysis of time series data may be used in the absence of specially collected longitudinal data.

Cohort and period are two of the dimensions which 'place' persons in time; the third is age. Duration effects (such as duration of marriage, proximity to death, or length of exposure to a particular pathogen) may also be important. Cohort effects may be substantial and, unless allowed for, may mask relationships between age and various risks. Differences in the smoking behaviour of cohorts, for example, have a major effect on the relationships between age and smoking-related disease observed at different periods (Grundy 1997).

Decisions about whether to use individuals, families, households, or geographic areas as units of analysis are often constrained by data availability. Until relatively recently, most census data were only available as aggregate tabulations, but individual-level information is increasingly available. Other innovations include the development of samples including linked census, vital registration, and in some cases health service data such as the Longitudinal Studies available for countries of the United Kingdom and a number of others (Young et al. 2010). In these data sets, individuals' census records are linked with their vital registration records so numerator–denominator biases in, for example, the analysis of mortality are avoided. In Nordic countries, the whole population has been assigned personal identification numbers facilitating linkage of information from a range of registers. Linkage to use of health and care services is also available in some countries, such as Finland.

These advances have greatly extended the material available for analyses of variations in demographic behaviour, and their consequences. They have also raised complex security and confidentiality issues fuelling debate over appropriate restrictions on access to data.

The measurement of fertility

Fertility means the childbearing performance of a woman, couple, or population. Generally only live births are included. The term fecundity, by contrast, is used to refer to the physiological capability of producing a live-born child. A rough idea of fertility may be gained from using census or survey data to calculate child–woman ratios: the ratio of 0–4-year-olds to women aged 15–49. However, the survival of infants (and their mothers) and the age structure of the female population affects these ratios, so they are generally only used if no other data are available.

The simplest measure of fertility commonly used is the crude birth rate—the number of births in a particular year per 1000 population. As the denominator of this includes those not ‘at risk’ of giving birth (women outside reproductive age groups and men), it is really a ratio rather than a rate. Crude birth rates are influenced by the age structure of the population, but less seriously so than crude death rates. In 2005–2010 crude birth rates ranged from less than 10 per 1000 in parts of Europe to nearly 50 per 1000 in the highest fertility countries of sub-Saharan Africa.

Slightly more sophisticated is the general fertility ratio—births per 1000 women of reproductive age (generally defined as aged 15–49 or 15–44). Where data allow, age-specific fertility rates (births per 1000 women of a particular age or age group) are preferred. These are frequently summarized using the total fertility rate (TFR). Where, as is usually the case, period data are used to calculate this, it indicates how many children women in a hypothetical cohort would have if they experienced current age-specific fertility rates throughout their reproductive life. This measure is sometimes explicitly denoted TPF_R (total period fertility rate). In low-mortality populations, a TFR of 2.1 is taken to indicate *replacement level* fertility as, under this regime, a cohort of women would be succeeded by a cohort of daughters of the same size (after some allowance for mortality and the fact that 105–106 boys are born for every 100 girls).

One difficulty with the TFR is that it is affected by changes in the ‘tempo’ as well as the ‘quantum’ of childbearing. If women start delaying their fertility but ‘catch up’ later, there will be a divergence between cohort and period measures, as the latter will be based partly on the behaviour of earlier cohorts whose timing of births was different. Similarly, if women have children earlier, TFRs will rise, even if eventual family sizes remain unchanged. This means that period measures are much more volatile than cohort ones. For example, the US TFR, having risen in the early parts of this century, fell by more than 10 per cent, from 2.12 to 1.89, between 2007 and 2011 (Hamilton et al. 2012). For these reasons, many statistical offices use cohort, rather than period, measures of fertility as the basis for projections.

More sophisticated measures of fertility include parity progression ratios. These indicate the probability of proceeding from one birth to another (e.g. what proportion of mothers with two children progress to having a third). Parity progression ratios are normally calculated for cohorts who have completed, or nearly completed, their childbearing but it is also possible to use data on births by birth order to derive period progression ratios (Bongaarts and Feeney 1998).

In the past, demographers often preferred to calculate age-specific *marital* fertility rates (and TFRs and other measures) on the grounds that the unmarried population is not ‘at risk’ (or at reduced risk) of childbearing. Changes in marital fertility indicative of deliberate attempts to limit family size are regarded as one

of the defining features of the fertility ‘transition’ (see later) and so distinguishing these from changes due to variations in the ‘at risk’ (married population) has been particularly emphasized. However, rises in non-marital childbearing, which now account for over 40 per cent of births in countries such as France, the United States, and United Kingdom, mean that restricting analyses to marital fertility is generally no longer appropriate.

Reproduction rates

In the absence of migration and with fixed mortality, populations will grow if mothers replace themselves with more than one (surviving) daughter and decline if they have fewer than one. Theoretically, it would also be possible to measure the replacement of fathers by sons, but in practice the difficulties involved in obtaining paternity data make this infeasible. Reproduction rates thus relate only to female fertility—births of daughters. The gross reproduction rate (GRR) is derived in the same way as the TFR except that age-specific birth rates based only on births of daughters are used in the calculation. The net reproduction rate (NRR) makes an allowance for mortality; specifically the chance that a daughter will herself survive to childbearing age. The NRR cannot be calculated unless both age-specific fertility and mortality data are available (although it can be approximated using the GRR and appropriate life table survival data). Changes in either fertility or mortality (or both) will mean a divergence between period measures (based on the experience of a hypothetical cohort) and the experiences of real cohorts.

Summary information on measures of fertility and reproduction is shown in Boxes 6.3.2 and 6.3.3.

The measurement of mortality

As for fertility, the simplest measure of mortality is the crude mortality rate, deaths per 1000 population. This is strongly influenced by age structure. Although life expectancy at birth in the more developed regions of the world in 2005–2010 was some 10 years longer than in less developed regions (76 years and 66 years respectively), crude death rates—deaths per 1000 population of all ages—were higher in the more developed regions (10.0 compared with 8.0 in less developed regions) (UN 2011). Age (and sex) specific rates, or measures based on them, are therefore much to be preferred if data are available to calculate them. Both direct and indirect standardization are sometimes used to make comparisons between populations with different age and sex structures. Standardized mortality ratios (SMRs) are calculated using indirect standardization. This involves selecting a set of ‘standard’ age-specific mortality rates, for example, those for a national population, and applying these to the numbers of people in the relevant age groups in the subpopulation of interest—for example, the population of a particular region. This yields an ‘expected’ number of deaths—the number of deaths there would be in the subpopulation if age-specific death rates were the same as those in the standard population. The ratio of observed to expected deaths gives the SMR. Thus an SMR of 1.24 indicates that mortality in the sub population is 24 per cent higher than in the standard population, after allowing for age differences. SMRs are useful summary measures of differences in mortality, but give no indication of the *level* of mortality. In direct standardization, widely used by WHO and national statistical offices, age and sex specific rates are applied to an external ‘standard’ population, such as the European Standard Population, to produce an overall standardized (weighted) death rate.

Box 6.3.2 Fertility measures**Definitions**

Fertility: the childbearing performance of individuals, couples, or populations.

Fecundity: the physiological capability of producing a live birth.

Parity: the number of children previously born alive (or sometimes number of previous confinements) to a woman or couple. Nulliparous women are those who have borne no children.

Measure

Crude birth rate: the ratio of births in a year (other specified period) to the average population in the same year/period (mid-year population), expressed per 1000:

$$\text{CBR} = \frac{\text{number of births}}{\text{mid-year population}} \times 1000.$$

General fertility rate: births to women aged 15–44/49 in a year/period per 1000 women aged 15–44/49 in the same period:

$$\text{GFR} = \frac{\text{number of births to women aged 15–44/49}}{\text{mid-year population of women aged 15–44/49}} \times 1000.$$

Age-specific fertility rate (ASFR): number of births to women aged x (or x to $x + n$) per 1000 women aged x (or x to $x + n$). 'n' refers to the length of an age interval.

ASFRs are frequently calculated for 5-year age groups from 15–19 to 40–44 or 45–49.

$$\text{ASFR} = \frac{\text{births to women aged } x}{\text{mid-year population of women aged } x} \times 1000.$$

Total (period) fertility rate (TFR/TPFR): the sum of the age-specific fertility rates for all reproductive age groups for a particular period (usually a year), conventionally expressed per woman. The TFR indicates how many children a woman would have if throughout her reproductive life, she had children at the age-specific rates prevalent in the specified year or period.

$x = 49$:

$$\text{TFR} = \sum_{x=15}^{x=49} f_x$$

where ' f_x ' is the age-specific fertility rate at age x . If rates for age groups, rather than single years, are used then the sum of the age-specific rates must be multiplied by the number of single ages included in the group (usually five).

$x = 45-49$:

$$\text{TFR} = 5 * \sum_{x=15-19}^{x=45-49} f_x.$$

Parity progression ratio: the probability of a women of parity x progressing to parity $x + 1$.

Box 6.3.3 Reproduction rates**Measures**

Gross reproduction rate (GRR): the sum of the age-specific female fertility rates (births of daughters), for all reproductive age groups for a particular period (usually a year) conventionally expressed per woman. The GRR indicates how many daughters a woman would have if, throughout her reproductive life, she had children at the age-specific rates prevalent in the specified year of period. The GRR can be calculated either by summing female age-specific fertility rates (relating to births of daughters rather than all births) or using the formula:

$$\text{GRR} = \text{TFR} \times \text{proportion of female births.}$$

The proportion of female births can be taken as 0.488 (100/205) in the absence of more detailed information.

Net reproduction rate (NRR): the average number of daughters that would be borne, according to specified rates of mortality and of bearing daughters, by a female subject through life to these rates. The NRR employs the same fertility data as the GRR, but also takes into account the effects of mortality. An NRR of 1.0 indicates that a population's fertility and mortality levels would result in exact replacement of mothers by daughters.

Age-specific death rates are calculated using the numbers of deaths at age x (or between ages x and $x + n$) in a particular year as the numerator and the mid-year population of the same age as the denominator. The rate is conventionally expressed per 1000 or per 100,000 population. The mid-year population is used as a measure of the average population at risk on the assumption that deaths are evenly distributed throughout the year. For some age groups, notably infants, this assumption is invalid. In low-mortality populations, deaths in the first 3 days of life may account for half or more of all deaths in the first year of life. Moreover, information on the size of population aged less than 1 normally comes from birth data (as in 9 out of 10 years relevant census data will not be available). For these reasons live births in a particular year are conventionally used as the denominator of the infant mortality rate while deaths to infants aged less than 1 constitute the numerator. Some infants dying in a given year will have been born in the previous year and some born in the year in question will die the following year. This can cause distortions if there are large annual fluctuations in numbers of births (or infant deaths) and often 3-year averages are preferred. Deaths at very old ages are also not evenly distributed throughout the year and an adjustment is often made to allow for this.

Infant mortality rates (IMRs) were very high in some parts of historical Europe—with 300 or even 400 deaths per 1000 live births in regions of Russia and Germany at the end of the nineteenth century (van de Walle 1986). In England and Wales at the start of the twentieth century, there were some 140 infant deaths per 1000 live births. Infant mortality in high-income countries is now extremely low—fewer than five infant deaths per 1000 live births in many European countries, Australia, Japan, South Korea, Hong Kong, and Singapore. There have also been huge falls

Box 6.3.4 Mortality measures**Measures**

Crude death rate: the ratio of deaths in a year (other specified period) to average population in the same year/period (mid-year population), expressed per 1000:

$$\text{CBR} = \frac{\text{number of deaths}}{\text{mid-year population}} \times 1000.$$

Age-specific mortality rate (ASMR): number of deaths to persons aged x (or x to $x + n$) per 1000 persons aged x (or to $x + n$):

$$\text{ASMR} = \frac{\text{deaths to persons aged } x}{\text{mid-year population of persons aged } x} \times 1000.$$

Standardized mortality ratio (SMR): the ratio of observed to expected deaths in a study population. Expected deaths are calculated by applying a set of standard age-specific mortality rates to the age distribution of the study population. Standardized ratios are only useful for comparisons. They have no intrinsic meaning.

Infant mortality rate (IMR):

$$\frac{\text{number of deaths to infants ages } < 1 \text{ year}}{\text{number of live births}} \times 1000.$$

Sometimes decomposed into *neonatal mortality rates* (deaths of live born infants during the first 4 weeks) and *post-neonatal mortality* (from 4 to 52 weeks).

The *perinatal mortality rate* measures late fetal deaths (stillbirths) and early neonatal deaths relative to live births.

$$\text{Perinatal mortality rate} = \frac{\text{stillbirths} + \text{deaths under 1 week}}{\text{still} + \text{live births}} \times 1000.$$

Stillbirths used to refer to deaths of fetuses of 28 or more weeks' gestation; however, an earlier threshold of 24 weeks is now more generally used.

in infant mortality in many poorer countries; in 2011 China and India had reported IMRs of 13 and 47 respectively (WHO 2013). Rates remain high in some of the very poorest countries—over 100 deaths per 1000 live births.

Variations on this scale have substantial demographic impacts. Infant mortality has also attracted particular interest because of links with fertility behaviour and as an indicator of public health conditions. Particularly in this latter context, perinatal, early and late neonatal and post neonatal mortality rates are often distinguished where data allow (see Box 6.3.4).

Life tables

Life table analysis is a core demographic technique and life tables provide one of the most powerful tools for analysing mortality

Box 6.3.5 Life table measures and notation

x = age attained last birthday.

l_0 = the radix of the life table (hypothetical number of babies), usually 100,000.

l_x = number of survivors at age x , so l_{65} is the number of persons alive at age 65 in the hypothetical life table population.

${}_nq_x$ = probability of dying between age x and $x + n$, so ${}_4q_1$ is the probability of dying between age 1 and 5 for a person aged 1.

${}_nP_x$ = probability of surviving between ages x and $x + n$, so ${}_{20}P_{65}$ is the probability of surviving from age 65 to age 85 for a person aged 65.

${}_nd_x$ = number of deaths between age x and $x + n$.

${}_nL_x$ = number of person years lived between x and $x + n$.

T_x = total number of person years lived after age x .

e_x = expectation of life at age x , so e_0 is expectation of life at birth.

and other demographic processes. Life tables show the probability of dying (and surviving) between specified ages. They also allow the calculation of various other indicators, including expectation of life. If complete data on the mortality of a birth cohort are available, then a cohort life table may be constructed. However, the use of cohort life tables is obviously only possible retrospectively. More commonly, period life tables, based on mortality rates at a particular time, are calculated. These life tables show death (and survival) probabilities for a hypothetical cohort with an arbitrary radix (number of babies at the beginning) usually set to 10,000, 100,000 or some other multiple of 100.

Specific notation, summarized in Box 6.3.5, is used in life table analysis. The basis of the table is a set of probabilities of dying— ${}_nq_x$ —which are calculated from age-specific death rates; x here refers to age at the start of an interval whose length is specified by n . Thus ${}_{5q}_{50}$ refers to the probability of someone alive at 50 dying between age 50 and age 55. The complement of ${}_nq_x$ —the probability of surviving—is denoted ${}_nP_x$. The (hypothetical) number of survivors at each age is given by l_x ; thus l_0 equals the radix (of 100,000) and l_{75} the number of survivors at age 75. The number of person years lived in an interval (${}_nL_x$) and the total number of person years lived after a particular age (T_x) are often not shown in published tables but are steps on the way to the calculation of e_x —life expectancy at age x .

This measure provides an indicator of mortality which is very largely independent of the age structure of the population since it depends only on age-specific mortality rates. This makes it more useful than either a standardized mortality ratio (which gives no indication of level) or a crude death rate (which is strongly influenced by age structure). Life expectancy either at birth (e_0) or further life expectancy at a particular age, say 65 (e_{65}), is calculated by dividing the total person years lived after age 0 or 65 (T_0 or T_{65}) by the number of survivors aged 0 (l_0) or 65 (l_{65}).

Values of life expectancy at birth are sometimes (mis)interpreted as indicators of usual age at death in a particular population. In very low-mortality populations where most deaths occur within a relatively small range of ages (see the example of Japan in Fig. 6.3.2); there will be a close correspondence between median and modal ages of death and life expectancy at birth (which is a mean value). However, in populations such as Sierra Leone where

so many deaths occur in infancy, there will be a wide divergence. There is also sometimes confusion about the interpretation of values of further life expectancy at a particular age. This is derived from information about the probabilities of death and survival at *subsequent* ages, and so is not influenced by deaths at earlier ages and it is erroneous to think that, for example, the further life expectancy of someone aged 65 will equal life expectancy at birth minus 65. The higher the mortality rates at young ages the greater will be this divergence. In 2008, for life example, female life expectancy at birth in the United States was 80.6 years but the further life expectancy of women aged 65 was 20.0 years. The equivalent figures in 1900–1901 were 49 years and 12.0 years.

Model life tables

Patterns of age-specific death rates show similarities whatever the level of mortality. Death rates tend to be higher in infancy than later childhood and rise with age from around the age of puberty, although in the oldest age groups rates of increase tend to flatten out. Because of the tendency for death rates at one age to be associated with death rates at other ages in a given population, it is possible to derive hypothetical schedules, called *model life tables*, describing variations in mortality by age and sex, normally in terms of a limited number of parameters which allow for particular features of the mortality pattern of the population considered. Model life tables are derived from empirical data from countries where these are available. They are extremely useful aids for the estimation of mortality by age in populations with defective data. They are also used (in conjunction with fertility data) to show the outcomes of particular fertility and mortality regimes on, for example, population age structure and for making population projections. All demographic texts give further details of their derivation and application.

Other applications of life table analysis

Life tables are widely used to analyse probabilities associated with events other than death, such as risks of divorce or contraceptive use failure and discontinuation rates, and in estimates of disability-free or healthy life expectancy. Many chronic conditions associated with ageing, such as musculoskeletal and sensory impairments, may have serious implications for health status but are not directly life-threatening. Life table methods are used to decompose total life expectancy into ‘healthy’ and ‘unhealthy’ or ‘disabled’ components. This can be done using cross-sectional data on morbidity prevalence in conjunction with mortality data, although this has some limitations. More sophisticated (and data demanding) multistate approaches which allow transitions both to and from disabled states have also been developed (Manton et al. 2006). Despite these technical advances, there is still controversy about *trends* in indicators of the health status of populations, including disability. To a large extent this debate arises from measurement problems and the difficulties involved in making comparisons between health indicators derived in different ways, a further reminder of the importance of data quality and measurement.

Multiple decrement life tables allow ‘decrements’ from more than one event—for example, different causes of death. Cause elimination life tables are also used to identify the ‘pure’ severity of a particular cause of death. Multistate models allow analysis of a range of transitions, particularly those where re-entries into a particular state, such as being married or living in a certain

region, are possible. These more sophisticated applications of course require more detailed data.

The measurement of migration

In many countries migration is the predominant influence on the spatial distribution of the population. In Asia and Latin America recent rural-to-urban migration has resulted in the phenomenal growth of cities, often lacking the infrastructure to meet the needs of the expanding population for basic services such as sanitation and power. In 2010, 52 per cent of the world’s population lived in urban areas compared with 29 per cent in 1950 (UN 2012).

Measuring migration represents particular difficulties. The classical definition of internal migration is a permanent or semi-permanent move across an administrative boundary, which means that the extent of migration recorded depends partly on the size of administrative areas. For example, in a country divided into many small areas, a move over 5 kilometres will count as migration, which would not be the case for countries divided into larger ones. Hence, international comparison of internal migration rates is potentially misleading. Even the distinction between international and internal migration may be problematic if boundaries are contested or changing. The temporal dimension to migration presents further difficulties; what constitutes permanent or semi-permanent and how should groups such as seasonal migrants be treated?

The reason for defining migration as a move over a boundary is largely pragmatic. Often only moves of this kind are recorded; moreover this is the information required by local administrations. For research purposes, analyses of *all* moves (preferably with an indication of distance moved) may often be preferred. Some countries have registration systems in which changes of address are recorded. More commonly, censuses are used to find out about migration. Questions on usual address 1 or 5 years ago allow the proportion of *movers* in the population to be measured (except for those aged less than 1 or 5). These data also allow inflows *and* outflows between pairs of areas to be measured. *Moves*, as opposed to *movers*, are not directly measured as someone moving several times in the reference period cannot be distinguished from someone moving only once. Those leaving an address and later returning to it cannot be identified either. This means that the length of the reference period used is important; the proportion of movers in the 5 years preceding a census will *not* equal five times the proportion moving in 1 year before the same census.

In the absence of direct census data, estimates of migration can be made indirectly using the ‘balancing equation’ referred to in the following subsection. Differences in the size of a population at two points in time not accounted for by natural change (i.e. births minus deaths) must be due to migration (or data errors). If vital registration data are available, then both births and deaths can be taken into account. If they are lacking, then the survival of groups enumerated in the first of a pair of censuses must be estimated from a life table and the number of expected survivors compared with the number enumerated in the second census (obviously ageing must be allowed for, so the number of 20–29-year-olds in the first census will be compared with 30–39-year-olds 10 years later). These methods only allow estimation of *net* migration (balance between in-migration and out-migration). Their major weakness lies in the fact that the residual population balance assumed to be

due to migration may in fact reflect differences in the quality of the two censuses considered or errors in the estimates of survival used.

Survey data are also used to measure migration and potentially provide illuminating information on the reasons for, and consequences of, migration. However, as migration over long distances is a relatively rare event, even large general population samples may yield relatively few migrants. A similar problem besets samples of international travellers, such as the UK International Passenger Survey, designed to estimate flows of international migrants through port or border surveys. Tourists and business travellers comprise the vast bulk of people entering or leaving so surveys are an inefficient way of identifying immigrants and emigrants. Unfortunately, other data are often lacking as legal and administrative record systems are frequently concerned with citizenship and right of abode rather than international migration per se (and virtually never with emigration). Estimates of the size of immigrant populations depend on whether the measure used is based on place of birth or on nationality—the size of the latter is influenced by policies on acquisition of citizenship.

Population dynamics

Any population comprises those who have made an entry and not yet exited. When whole populations of defined geographic areas are considered, the only means of entry are birth or immigration and the only means of exit death or emigration.

The most basic method of demographic analysis is the decomposition of overall population change ($P_t - P_0$) into its components (B, D, I, E):

$$P_t - P_0 = B - D + I - E$$

where P_t = population at an end of period; P_0 = population at the beginning of a period; and B, D, I, E represent respectively births, deaths, immigrations, and emigrations during the same period ($B - D$ is referred to as natural increase and $I - E$ as net migration). Population subgroups may be similarly defined in terms of entries and exits. In the absence of migration, entry to the population aged 75–84 is through ageing (passage from 74 to 75) exit is through further ageing (84 to 85) or death. This simple accounting equation is an important one, both methodologically and as a formal reminder of the need to consider *past* as well as current events.

Of the three demographic determinants of population size, structure, and growth, fertility has historically been of much greater importance than either mortality or migration. Every birth represents not just an addition to the current generation of children, but also potentially an exponentially increasing augmentation in the size of future generations. Death carries no such promise of future return. Births increase the population only at age zero, so making it younger, whereas deaths are spread across the whole age range and so have much less impact on age structure. The third determinant—migration—is generally not of significant magnitude to have a major impact on most national populations, although there are exceptions especially when natural increase is close to zero. Increased levels of immigration to many European countries since the 1990s have had quite an effect on population size and age structure; the population of Spain for example,

increased by 10.2 per cent between 1999 and 2006 and over 90 per cent of this increase was due to migration (Sobotka 2008).

For social and biological reasons fertility, mortality, and migration have interactive effects. Decreases in mortality among those with reproductive potential, for example, influence not just the size of the age group affected at the time, but also the size of succeeding generations. Declines in male mortality, particularly in populations where large age differences between spouses are common and remarriage of widows is rare, will similarly tend to increase fertility by effectively increasing the proportion of women of reproductive age who are still married. Conversely, reductions in fertility clearly reduce the risk of maternal mortality and may have further positive effects on the survival of mothers, infants or both. Age at motherhood also influences rates of population growth. The average age of mothers at the birth of their daughters is termed the mean length of a generation and is generally around 29 years. A shorter interval will mean more rapid generational succession (and faster population growth).

Migration affects other demographic parameters because migrants differ from the general population. International migrants are generally young and in good health and often move from relatively high- to low-fertility populations. Consequently, immigrants may serve to (temporarily) 'rejuvenate' the host population and, at least initially, have higher fertility and lower mortality. In England and Wales, for example, 24 per cent of births in 2011 were to mothers themselves born outside the United Kingdom. Despite the disadvantages they often face, mortality of immigrant groups is often lower than that of host populations because of the differential selection of immigrants. The degree of selection tends to vary according to difficulties and distance to be overcome in making an international move. For all these reasons, the demographic characteristics of population subgroups largely comprising immigrants and their immediate descendants may vary substantially from those of the population as a whole.

Population projections

Population projections represent one of the most widely used outputs of demographic analysis. Strictly speaking, a projection simply represents the outcome of applying various assumptions about future fertility, mortality, and migration and so differs from a *forecast*, which implies prediction. However, projections are often treated as forecasts and the degree of uncertainty inherent in them is not always sufficiently recognized, although the production of probabilistic forecasts, as in the latest UN projections, makes this more explicit. The most common method of projection is the component method, based on the balancing equation ($P_t = P_0 + B - D + I - E$). Assumptions are made about the three components of change—births, deaths, and migration—and applied to age and sex groups within the initial population to give a projection of future size and structure. To a large extent assumptions are based on recent trends together with other information, for example, survey data on fertility intentions or (sometimes) models of change in particular causes of death. Forecasting fertility has generally been regarded as the most problematic area of projection but recently greater attention has been paid to the errors that have been made in forecasting mortality in developed countries. This has little effect on age groups in which survival is high, but can have quite substantial impacts on forecasts of the number of older people. Migration may be an important element and may

be underestimated, if projections do not take into account feedback loops whereby migrant populations tend to generate further migration (Bongaarts and Bulatao 2000). International migration is also difficult to forecast as it is affected by events outside the country, is often a sensitive political issue and may be volatile. Partly for these reasons, immigration levels have been consistently under-projected in forecasts in many European countries (Alders et al. 2007).

Population growth

Changes in the size of a population produced by the surplus (or deficit) of births over deaths are termed natural increase (or decrease). A common indicator of growth is the crude rate of natural increase—the difference between the crude birth rate (annual births per 1000 population) and the crude death rate (annual deaths per 1000 population). If net migration is zero, this will be the same as the growth rate of the population—the overall annual change in the population divided by the population size—(conventionally expressed as a percentage). In several European countries deaths outnumbered births in the period 2005–2010, with the largest deficits in Ukraine, Bulgaria, Latvia, Belarus, Hungary, Lithuania, and the Russian Federation. In some others births still outnumber deaths even though fertility rates have been below the level required for *long-term* replacement for 40 years or so. This apparent paradox largely reflects the fact that the number of births is a function of the number of potential mothers, to which immigration may also contribute, as well as of their fertility patterns. If the former is increasing so too may the numbers of births, even if women have fewer children each.

The young age structures of many populations in the developing world mean that these populations have a huge built-in potential for growth. Population *momentum* is the measure which gives the ratio of the ultimate size a given population would achieve to current population size if fertility were to immediately fall to replacement level. Even allowing for the effect of HIV/AIDS-related mortality, the population of sub-Saharan Africa is expected to increase from 0.86 billion to 1.96 billion between 2010 and 2050 (UN 2011), a consequence of both population momentum and high levels of fertility. In some low-fertility countries there are now concerns about ‘negative momentum’—the prospect of decline in population even if fertility rates increase somewhat because of successively smaller cohorts of women in childbearing age groups.

Intrinsic rate of natural increase: stable population theory

Early in the twentieth century, Lotka (1907) demonstrated mathematically that a population closed to migration and subject to unchanging age-specific fertility and mortality rates for a long period would eventually have a fixed age structure (in which the proportion in each age group remained unchanged) and would grow at a constant rate. This type of population is called a *stable* population. The fixed age structure of a stable population is independent of the initial age structure—two very different populations subject to the same unchanging rates for a long period would eventually assume the same structure. A particular case of a stable population is a *stationary* population—one in which birth and death rates are constant and in balance and so population growth is zero. The L_x column of the life table is an example of a stationary

population. The number of births is fixed (the radix) and the age distribution is also fixed. In non-stationary stable populations, the age structure is also fixed but the size of every age group is growing at the same constant rate as the overall population and the number of births. This is called the *intrinsic rate of natural increase* and is a function of the net reproduction rate and the mean length of a generation (approximated by the mean age of childbearing). Non-stationary stable populations can be calculated by adjusting the L_x values of a particular life table to allow for the intrinsic rate of growth. These are often published in conjunction with model life tables to show the effects of particular (unchanging) fertility and mortality regimes.

Although stable and stationary populations are theoretical constructs, real populations at various times have met the model requirements closely enough to allow stable population theory to be used to develop methods for indirectly estimating fertility and mortality in populations lacking adequate directly derived data. Stable population models are also widely used for insurance, pension, and personnel planning. One of the important results of the work of Lotka and his successors was to show theoretically the important influence of fertility on age structure.

Age structure

Population pyramids graphically illustrate the current structure of populations and in so doing, also provide insights into both the future and the past of the population. High fertility populations have a pyramid shape with each successive cohort being larger than its predecessor. The population pyramid for Bangladesh (Fig. 6.3.3A) shows a typical pattern for a population with a history of high fertility but a recent downturn. Each successive cohort is larger than the preceding one, with the exception of the youngest. ‘Old’ populations, such as that of England and Wales (Fig. 6.3.3B), are more rectangular with a gradual tapering at the top. Bulges in population pyramids due to high numbers of births have ‘echo’ effects when members of large cohorts themselves have children. Thus the baby boom experienced in many populations in the post-Second World War period (precise timing varied between countries) had an echo effect in the 1980s.

Historically, and apparently paradoxically, improvements in mortality in those European populations which now have high proportions of old people in fact served to *offset* the trend towards population ageing, as they chiefly benefited the young—and led to increases in the proportions surviving to have children themselves. However, although fertility has the greatest *potential* impact on age structure and population growth, in some circumstances mortality (or migration) may become a more important influence. Many populations in richer countries now have fertility at or below replacement level, life expectancies at birth close to 80 and near universal survival to the end of the (female) reproductive span. In these conditions, further improvements in mortality have the greatest impact at old ages and further population ageing occurs from the apex, rather than, or in addition to, the base of the population pyramid. Mortality changes are now the main motor of the further ageing of a number of populations with already old age structures (Preston and Stokes 2012). Population age structures and associated rates of growth or decline, changes in age structures such as population ageing, and the speed and stage of age structural change all have important economic and

Fig. 6.3.3 Distribution of the population of (A) Bangladesh and (B) the UK by age and sex, 2010.

Source: data from United Nations, *World Population Prospects: The 2010 Revision*, United Nations, New York, USA, Copyright © 2012, available from http://esa.un.org/wpp/documentation/pdf/WPP2010_Volume-I_Comprehensive-Tables.pdf

health implications which have attracted considerable debate and controversy.

Many economists have pointed out that population growth has often provided a spur to human ingenuity and economic growth. Less positively, the countries which now have the youngest age structures and most rapid rates of population growth are already suffering from land degradation and in many cases, constrained agricultural potential (Alexandratos 2005). Large and growing child populations also hamper efforts at improving human capital through education or improved health (Casterline 2010).

Reduced fertility initially produces a 'demographic dividend' or 'window' when the ratio of children to adults falls and those in prime productive ages, the survivors of larger birth cohorts, account for a higher proportion of the population. It has been argued that this dividend of lower child dependency and higher representation of adults in the prime working age groups played an important part in the rapid economic development of the 'East Asian Tigers', like South Korea and also China (Bloom et al. 2000). The next phase, involving high and increasing representation of older people may, it has been suggested, also bring some economic benefit in the form of increased savings (by the large number of older people) and so greater capital available for investment (Mason and Lee 2006). However, population ageing is more often perceived as a challenge with potentially negative implications for both the economy and for population health (OECD 1999).

The major concerns arising from increases in the proportions of older people relate to effects on productivity and need for support systems of various kinds, including pensions, healthcare and long-term care. In OECD countries, healthcare expenditure is typically three to five times as high for those aged 65 and over as for those aged under 65. However there is considerable international variation in the proportion of GDP devoted to healthcare spending for older people which bears little obvious relationship to the proportion of older people in the population concerned.

In populations which have more recently moved to low fertility and low mortality regimes, the pace of demographic change has been much faster than occurred historically in Europe. The proportion of the Japanese population aged 65 and over doubled, from 7 per cent to over 14 per cent, between 1970 and 1996. In France a similar increase took 130 years to achieve and in Sweden 85 years (Kinsella and Phillips 2005). More recently ageing populations have thus had a much shorter period in which to adapt to new public health priorities. The origins of these age structure changes lie in the demographic transition.

The demographic transition

Towards the end of the nineteenth century (earlier in France) birth and death rates started falling in a number of European countries. Between 1871–1875 and 1911–1915 the TFR for England and Wales, for example, dropped from 4.8 to 2.8; by the early 1930s it was below replacement level, a development which was viewed with alarm and led to the first Royal Commission on Population. Although modern methods of contraception were lacking, it was clear that this huge drop in fertility was the result of the deliberate limitation of family size. Half of couples married in the 1870s had six or more children compared with 12 per cent of couples married in 1911–1915 (Coleman and Salt 1992). Expectation of life at birth, meanwhile, increased by some 15 years between the end of the nineteenth century and the early 1930s.

Researchers attempting to relate such shifts in demographic regimes to economic and social changes, originated the theory of the demographic transition. The 'classical' view propounded by Notestein (1945) and others was that in 'traditional' societies fertility and mortality are both high and roughly in balance. Change is driven by economic advance which results in lower mortality. Fertility initially remains high, resulting in a rapid period of population growth. After this lag, however, fertility also falls

in response to falling mortality and the erosion of 'traditional' pro-natalist values.

This classical view has since been considerably modified (Lee 2003). Coale and his collaborators in an ambitious project to track the transition in historical Europe suggested that no economic 'threshold' for fertility decline could be identified and that the pattern of decline seemed to follow regional groupings, suggesting a cultural rather than a socioeconomic dimension (Coale and Watkins 1986). Falls in infant mortality, assumed to be a particularly important stimulus to fertility decline, sometimes followed rather than preceded changes in fertility. For example, Woods et al. (1989) argued that declines in fertility led to reductions in infant mortality, rather than vice versa in England and Wales. In short, the role of mortality decline as a trigger and the dominance of economic change have both been questioned. Caldwell (1982) additionally argued that in non-European countries, it was not so much socioeconomic modernization but 'Westernization' involving increased emphasis on the nuclear family and a change in intergenerational wealth flows (resulting in the costs of children outweighing their potential benefits) that was the important trigger of fertility transition.

Research on the historical demographic transition in Europe may seem of limited relevance to contemporary problems. However, this research was fuelled by post-war fears about population growth. By 1950, significant mortality declines had been achieved or initiated throughout the world. In China, for example, expectation of life at birth increased from 43 in 1960 to over 75 by 2010. Even in sub-Saharan Africa, a gain of nearly 10 years—from 43 to 52—was achieved between 1950 and 1990, sadly since reversed although now starting to increase again (World Bank 1993; UN 2011). In this context it seemed imperative to discover the causes of fertility decline and use this knowledge to accelerate fertility 'adjustment' to falling mortality. Was 'development the best contraceptive' as concluded at the stormy 1974 World Population Conference; could change be achieved through intensive family planning programmes, as the experience in Taiwan and South Korea seemed to suggest; or was some combination of these and other factors the key to fertility transition? Studies of societies in which the fertility transition had occurred seemed to offer the best prospect of an answer to these questions. While simple answers to complex questions are rarely forthcoming, Coale (1973) identified three factors which he considered prerequisites for fertility decline in contemporary populations. These were: that potential parents must think it acceptable to balance the advantages and disadvantages of another child, that some advantage must be gained from reduced fertility, and that effective techniques of fertility control must be available.

Trends in fertility in the second half of the last century and early part of this century have shown considerable divergence and shed some light on these debates. TFRs are highest in sub-Saharan Africa, with Uganda, Somalia, Mali, Timor-Leste, and Niger having TFRs above 6.3 in 2005–2010. In all other world regions there was clear evidence of onset of a transition to lower fertility by the 1970s or 1980s; Japan was the first non-Western country to experience a fertility transition starting after the Second World War. Globally, the estimated TFR in 2005–2010 was 2.52, with 48 per cent of the world population living in countries with below-replacement fertility levels (UN 2011). Substantial fertility declines have occurred in a number of countries which at that time had only a limited amount of development, such as Sri

Lanka, Thailand, China, and more recently Bangladesh. One of the largest and fastest fertility declines took place in the Islamic Republic of Iran where fertility fell from 7.0 in 1980 to 1.9 in 2006 (Abbasi-Shavazi et al. 2009) defying assumptions that socially and religiously conservative Muslim societies with low rates of female employment would be resistant to fertility change.

Recent interpretations of fertility change have reverted to considering development—in its broadest sense rather than restricted to consideration of average incomes—a stronger influence in contemporary populations than ideational changes, although the relevance and role of cultural and policy related factors is recognized (Bryant 2007). Common factors identified in poor rural populations where fertility has fallen significantly are well-established education systems, improvements in healthcare and in child survival, some form of extra-familial welfare, well-organized local government, and an organized family planning programme. Potential benefits of investing more resources in fewer children, as a consequence of increasing opportunities in urban or industrial livelihoods, also seem to be important (McNicol 2006; Bryant 2007). The education of women has been identified as a particularly significant influence on both falling fertility and improved infant survival (Cleland 1990; Hobcraft 1993) and female education and empowerment were recognized as key policy objectives at the 1994 International Conference on Population and Development (UNFPA 1995).

As noted earlier, fertility rates remain high in much of sub-Saharan Africa. Continuing expressed preferences for large families and other family and social characteristics of African populations have led some to conclude that the model of change seen in Asia and Latin America may not be applicable to Africa, or at least not to all regions of Africa (Caldwell et al. 1992). There is nevertheless evidence of unmet demand for family planning and a strong case can be made, on the grounds of improving maternal and child health, for renewed investment in family programmes which in some places faltered as the policy focus and funding shifted to the HIV/AIDs crisis (Cleland et al. 2006).

Recent trends have also made it clear that the end point of fertility transition is not necessarily a fertility level around the 'replacement rate'. In some countries, such as Guatemala, Peru, Egypt, Turkey and Ghana, fertility declines 'stalled' (sometimes temporarily) at a level higher than two children per woman (Bongaarts 2005). In others they have continued downward spiralling, giving rise to a new set of concerns about 'lowest low' fertility.

Lowest low fertility and the second demographic transition

In contrast to the scenario of high fertility and rapid population growth in some of the poorest countries, a growing number of high-income countries now have concerns about the implications of low fertility. Many of these countries experienced a post-Second World War 'baby boom' during the 1950s and early 1960s followed by a 1970s 'baby bust' when fertility declined to very low levels. In Scandinavia, France, the United Kingdom, the United States, and other English-speaking countries fertility rates have since fluctuated at levels between 1.6 and replacement level with something of an increase in the first decade of this century—a pattern also seen in many other industrialized countries—however, this may turn out to be a

temporary phenomenon particularly given current economic conditions. These populations have also experienced a range of family-related behavioural changes, included marked increases in cohabitation, non-marital childbearing, divorce, postponed childbearing, and increased levels of childlessness, described by some as a 'Second Demographic Transition' (Lesthaeghe and Neidert 2006). Such behaviours, which have become more usual among Northern European cohorts born from around the 1950s onwards, are much less prominent in Southern and Eastern Europe and the richer countries of South and East Asia. However, it is mainly in these latter countries that 'lowest low' fertility—rates below 1.3—has been prevalent with 21 countries from these regions having TFRs below 1.3 in 2003 (Goldstein et al. 2009). The recent increase in fertility in developed societies meant that only three of these countries, South Korea, Slovakia, and Singapore, had average values below 1.3 in the period 2005–2010 (UN 2011). However, the TFR remained below 1.5 in a large number of other countries including Poland, Japan, Germany, Italy, Ukraine, Spain, and the Russian Federation in 2005–2010. An important determinant of very low fertility in many of these societies has been a precipitous fall in marriage rates (Billari and Kohler 2004). Japan, for example, has been transformed from a society with near universal marriage in the early and mid twentieth century to one in which a fifth of the population will remain never-married at age 45 (Retherford et al. 2001). In this case the erosion of arranged marriages after the Second World War has played a part; changing gender roles may also be important. In some countries with very low fertility, explicit pro-natalist policies are under discussion or have been introduced, however these remain controversial and of unclear effectiveness.

The proximate determinants of fertility

One of the contributions of research into the fertility transition has been improved understanding of biosocial influences on reproduction. A huge range of social, economic, cultural, and psychological factors may influence decisions about family building strategies and family size. However, these can only have effect if they are translated into patterns of behaviour or physiological characteristics that influence the risks of conception or delivery.

Conversely, other patterns of behaviour with potentially important influences on fertility may be adopted with little or no thought to these consequences. Davis and Blake (1956) distinguished a series of 'intermediate fertility variables': factors influencing exposure to risk of pregnancy (marriage and coital frequency), risk of pregnancy (such as contraception), and pregnancy outcome (spontaneous and induced abortion). The most influential refinement of this work is the Bongaarts decomposition model (Bongaarts 1978), which identified four elements chiefly responsible for observed fertility variations:

- ◆ The proportion of women married (exposed to risk).
- ◆ Contraceptive use.
- ◆ Induced abortion.
- ◆ Post-partum non-susceptibility to conception (largely determined by breastfeeding practice).

The TFR is dependent on the interactive effect of these variables and hypothetical maximum fertility. In modern 'post-transition' populations, fertility decisions are normally couple- (or woman-) based and are implemented through contraception and abortion. In non-contracepting populations, biosocial factors, notably marriage patterns, breastfeeding practices, sexual frequency and, in some populations, the prevalence of infertility, are of major importance.

The social reproductive span, from entry to end of marriage or any sexual union, nearly always starts later, often much later, than menarche. Fecundity—the potential for bearing children—decreases after the third decade, more sharply after the age of 35 and in most non-contracepting populations the average age at last birth is around 40. Social factors, as well as biological ones, are important influences. Sexual activity may cease before menopause because of widowhood or separation. In some African populations, childbearing after becoming a grandmother is disapproved of.

For those within the effective reproductive span—biologically capable of childbearing and in a sexual union—overall fertility is largely a function of length of intervals between births, itself largely determined by breastfeeding patterns. Among non-breastfeeding women, average duration of post-partum amenorrhea is only 1.5–2 months, compared with 18 months or more with protracted breastfeeding, particularly in some populations where sexual activity is proscribed for breastfeeding mothers.

Longer birth intervals and increased breastfeeding also have positive effects on infant and child health. Overall deaths before the age of 5 might be reduced by as much as 30 per cent in some countries if closely spaced births were delayed (World Bank 1993; Cleland et al. 2006).

The epidemiological transition

Transitions from relatively high- to low-mortality regimes have in all populations been associated with transformations in the age, cause, and sex structure of death. Omran (1971) coined the phrase 'epidemiological transition' to describe this process. Changes in the response of societies to health and disease processes also need consideration. The term 'health transition' has been proposed as one which embraces both these phenomena.

Substantial falls in death rates from infectious and parasitic diseases and maternal mortality are hallmarks of the epidemiological transition. In England and Wales, over half the gain in life expectancy at birth between 1871 and 1911 was due to reduced infectious disease mortality. Some 20 per cent of the total gain was due to reduced death rates from tuberculosis (Caselli 1991). Declines in these causes of death were greater among the young, hence deaths at older ages accounted for a larger share of all deaths; the epidemiological transition has also been consistently associated with larger falls in mortality among women than men. Changes in the intra-household allocation of resources, declines in causes of death primarily affecting women (such as maternal mortality and respiratory tuberculosis), gender differences in health-related behaviour and in exposure to occupational hazards, and the possibly greater susceptibility of men to stresses associated with socioeconomic changes, may all be underlying factors.

The relative contribution of various eighteenth- and nineteenth-century developments in promoting the historical epidemiological

transition in the West remains a matter of debate. Improved nutrition, better housing and living conditions, public sanitation schemes, and specific public health initiatives, such as smallpox inoculation, all have their adherents. In the early twentieth century, improved personal hygiene practices and better infant care were also important. A common thread linking most of these factors is their relationship to overall social and economic development and improvements in standards of living. During the twentieth century, however, developments in medical technology and vector control offered the potential for 'exogenous' mortality decline less dependent on a particular country's level of income and development. One consequence was that the relationship between per capita income and life expectancy has shifted to the right (Preston 1975, 2007). In 1901, for example, life expectancy in the United States was 49 and income per capita was about US\$7300 (2005 purchasing power parity). In 2009, income per capita in China was almost identical (\$7400) but life expectancy was 73 years (<http://www.gapminder.org/>).

Many poor countries have been able to achieve remarkable falls in mortality, especially child mortality, through behavioural change, improved education of women, and introduction of relatively cheap treatments and interventions, such as vaccination and antibiotics (Cutler et al. 2006). Between 1975–1980 and 2005–2010 life expectancy at birth increased from 53 to 68 in Bangladesh and from 56 to 68 in Indonesia (UN 2011) and there are now a number of poor or middle-income countries with life expectancies at birth as high as in the United States.

The process of the epidemiological transition (or at least the initial phases) is now complete or under way in much of the world and non-communicable causes of death predominate in all regions except sub-Saharan Africa (see Table 6.3.2). However, some recent changes have been less benign and new challenges or reversals have emerged, notably the HIV/AIDS epidemic and the health consequences of the collapse of the former Soviet Union (Olshansky et al. 1997; Murphy 2011). Partly because of these challenges, there are signs that after a period in which risks of mortality in different parts of the world showed a tendency to converge (i.e. poorer countries caught up with richer ones), more recently there has been a trend towards divergence. Another factor in this may be that recent successes in richer countries in, for example, lowering mortality from heart disease, have partly been achieved through treatments which are harder to 'transfer' to poor countries because of infrastructure and cost limitations (Vallin and Mesle 2004; Ford et al. 2007).

Recent demographic trends and public health

Population size, growth, and age structure are all outcomes of variations in demographic behaviours and all have implications for population health and well-being. Population ageing will almost certainly be the predominant demographic issue of the twenty-first century in nearly all richer and a growing number of poorer countries. The strong association between age and risks of health impairment and disability imply growing needs for support services, even if levels of disability fall. In those countries which are growing old before they grow rich, changes in family support systems for older people may pose additional challenges. A range of strategies for responding to these challenges has been

proposed, including encouraging longer working lives through review of retirement and pensions policies, better organization of acute and long-term care services, and initiatives to promote healthy ageing (Rechel et al. 2013).

Changes in marriage and family patterns also have other public health implications. In North America and North West Europe (and also Latin America and the Caribbean) high rates of divorce and non-marital childbearing mean that increasing proportions of children are spending at least part of their childhood in lone-parent families. Although causal pathways are difficult to elucidate because of various selection effects, there is evidence indicating poorer health among lone mothers and their children, and among unmarried (especially divorced) people more generally, so these trends have some negative implications.

Continuing improvement in child and adult mortality is projected for the poorer world, based on optimistic assumptions about the course of the HIV/AIDS epidemic. In the poorest countries the interaction of rapid population growth, environmental degradation and conflict pose continuing health problems and the 'unfinished agenda' in terms of health includes providing access to contraception for women who wish to space or limit their children (Cleland et al. 2006). In other middle- and low-income countries, patterns of tobacco use are likely to have a substantial effect on health trends in coming decades (West 2006).

Issues such as international migration, economic and cultural 'globalization', and climate change all have substantial health implications for the rest of the twenty-first century; all interact with demographic patterns and processes. Measuring these trends and assessing their effect on health and demand for healthcare requires an understanding of population dynamics and population-based measures, and suitable demographic data. Demography is thus an essential component of public health.

Health promotion, health education, and the public's health

Simon Carroll and Marcia Hills

Health promotion, health equity, and action on the determinants of health: an introduction

Previous attempts (Green and Raeburn 1988; Tones and Tilford 1994; Tones 2002) to situate health promotion within the broad field of public health have often used 'health education' as the starting point. This is an entirely sensible approach which we will discuss but it tends to underemphasize the *radical* departure health promotion aims to make from traditional public health approaches in general. Without claiming health promotion means everything all at once, thereby leaving its lofty rhetoric in the realm of the aspirational yet ineffectual, we aim to place health promotion more centrally in the ongoing saga of an increasingly globally aware public health. As one of the acknowledged founders and innovators of the modern health promotion movement has unceasingly argued, health promotion, at its most persistent and radical, heralds a 'new public health', not merely a more fine-tuned and effective tool-box for a less paternalistic health education (Kickbusch 1989, 2007).

We will begin with a clear definition of health promotion. Then, by unpacking the dense and sometimes opaque wording that define the elements of health promotion as a concept, we intend to open up some of its central, yet often hidden, connections to much broader themes in contemporary social and political movements and ideas.

Next, we situate health education and its internal critique as an important part of the history of health promotion, while providing more context concerning the specific historical/national trajectories that made the genesis of the modern health promotion movement a mixture of different influences, of which health education is only one.

We will consider how health promotion manages its ambiguous relationship with the history and ideological background of public health, and how it sees itself in relation to the past, present, and future of public health.

We suggest there is a new opportunity for health promotion to reconnect with the avant-garde in public health, which can be examined along two broad dimensions, namely how to achieve health equity, and the question of health in a global political-economic context. Particular attention will be paid to the

recent work following up the World Health Organization (WHO) Commission on the Social Determinants of Health, led by Sir Michael Marmot, and the renewal of the *Ottawa Charter* action area of 'healthy public policy' in the *Health in All Policies* global movement, spearheaded by the WHO.

In a previous version of this chapter (Hills and Carroll 2009), we argued that there was an under-analysed political economy of health promotion; in this revision, we argue that this is partly to do with the relative lack of engagement with social theory within the health promotion field. We offer some suggestions and map out potential pathways towards more serious reflection on this missing social-theoretical base. Finally, we consider the emerging role of complexity theory and systems thinking in health promotion research.

In general, this chapter on health promotion is *critical* in the positive sense of the word. Previous surveys of the concept and practice of health promotion that provide excellent guidance to the field are referenced. However, we consider that practitioners and researchers in public health can benefit from a reflexive inquiry into the rich ambiguities and tensions that are embedded in the discourse and practice of health promotion. This is particularly the case if, as we argue, the development of health promotion is the development of a 'new public health'.

'Health promotion': a definition and conceptual critique

In this chapter, we will follow the *Ottawa Charter for Health Promotion* (WHO 1986) definition of health promotion as 'the process of enabling people to increase control over, and to improve their health'. However, we will also draw upon the expanded definition in the updated *Health Promotion Glossary*:

Health promotion represents a comprehensive social and political process, it not only embraces actions directed at strengthening the skills and capabilities of individuals, but also action directed towards changing social, environmental and economic conditions so as to alleviate their impact on public and individual health. Health promotion is the process of enabling people to increase control over *the determinants of health* and thereby improve their health. (WHO 1998, our emphasis)

Here, the 'how' and 'why' *ideology* is linked to the 'what' of the *determinants of health* (WHO 1998). This is crucial, because if health promotion is about anything, it is about *action* taken across the broad spectrum of health determinants, particularly directed towards the social, environmental, and economic conditions that support health (WHO 1984).

The *Glossary* also emphasizes that 'participation is essential to sustain health promotion action', and identifies the three *Ottawa Charter* strategies for health promotion: 'Advocacy for health to create the essential conditions for health indicated above; *enabling* all people to achieve their full health potential; and *mediating* between the different interests in society in the pursuit of health.'

These strategies are supported by five priority action areas as outlined in the *Ottawa Charter*:

1. Build healthy public policy.
2. Create supportive environments for health.
3. Strengthen community action for health.
4. Develop personal skills, and
5. Re-orient health services. (WHO 1986)

As one can see from these definitions, we already have started the 'unpacking'. A more nuanced analysis of some of the key elements in this definition is described in the following subsections: the 'process' of health promotion; 'enabling' and 'empowering'; and for what, the outcome, 'improved health'. This will be followed by an analysis of the *Ottawa Charter strategies* and its *priority action areas* (often called 'action strategies').

As soon as we begin, we find ourselves in murky waters, though not without some guidance. Ironically, although health promotion is, as Tones (2004) noted, an 'essentially contested concept', there has been a remarkable degree of effort, and consensus, concerning its ostensive definition. Few, if any, health promoters dispute the *Ottawa Charter's* now canonical phrasing (WHO 2005).

The real ambiguity that surrounds the concept of health promotion is embedded in the elision of the concrete meaning of the elements that make up its agreed upon definition.

Health promotion as a process

The emphasis on *process* is important, if only because it warns against reducing health promotion to merely a technical function of public health. It connotes the wider meaning of the concept by signalling that the radical departure and critique of traditional public health lies in its advocacy for changing the *way* we do public health, just as much as *what* we change and *why* we change.

Health promotion, whether it be generated from an internal critique of health education or from other dissatisfactions with the way public health was being practised, is fundamentally concerned with change and, specifically, with the failure of traditional, paternalistic, and professionally dominated public health processes to bring about positive changes in health, particularly for those groups that suffer disproportionately negative health outcomes and the consequent disadvantages. What is substituted is a call for health promoters to create a dynamic, participatory engagement with individuals and communities, to help or 'enable' them to take control over the determinants of their own health.

The first ambiguity we meet when trying to analyse this 'process' turns on whether one interprets the health promotion

process as, primarily: a revamped tool-box of health education techniques and social marketing devices, with a rhetorically efficient participatory gloss; or, as a values-based process of communicative interaction that has as its central premise the ethical foundation of respect for human dignity and autonomy. These are certainly polar extremes and there is no doubt that there is room for both aspects in a broad, ecumenical attitude to a diverse field of practical action. Yet, because health promotion is a process often dominated by professionals, in a context where its supposed beneficiaries are often those in a position of relative powerlessness, the tendency for professionals to retreat to an insulated cocoon of technical expertise is strong. The essence of the health promotion process is a focused shift of power from professionals to the community and to individuals within their communities who historically have had less power. To do this, it is crucial that the 'process' we focus on is the one that involves negotiating values, principles, ethics, and power, not the less complicated one of transferring a packet of new skills and technical tools to a community that is presumed to lack capacity. In order to achieve this shift in power, health promoters need to begin by examining their own values and assumptions that inform their actions.

Beliefs and assumptions underlying health promotion

Health promotion practice is influenced by the beliefs and assumptions we hold. While a detailed discussion of this topic is beyond the scope of this chapter, we outline how certain beliefs and assumptions influence how we act in health promoting ways in given situations.

Beliefs are learned through life experiences; they are what we hold as 'true'. They are convictions that influence the way we think, feel, and act. Health promotion practice relies on a set of underlying assumptions that guide those who work in the field. Hartrick et al. (1994) contend health promotion is a 'way of being' that requires certain convictions in order to act in health promoting ways. These include:

1. All people have strengths and are capable of determining their own needs, finding their own answers, and solving their own problems.
2. Every person and family lives within a social-historical context that helps shape their identity and social relationships.
3. Diversity is positively valued.
4. People without power have as much capacity as the powerful to assess their own needs (people are their own experts).
5. Relationships between people and groups need to be organized to provide an equal balance of power (this includes professional/client relationships).
6. The power of defining health problems and needs belongs to those experiencing the problem.
7. The people disadvantaged by the way that society is currently structured must play the primary role in developing the strategies by which they gain increased control over valued resources.
8. Empowerment is not something that occurs purely from within (only I can empower myself), nor is it something that can be done to others (we need to empower the group). Rather, empowerment describes our intentional efforts to create more equitable

relationships where there is greater equality in resources, status, and authority.

9. Shared power relations do not deny health professionals their specialized expertise and skills. Rather, professional expertise and skills are used in new ways that result in greater power equity in interpersonal and social relations. (Hartrick et al. 1994, p. 87)

So, for example, if we consider the first assumption in the list, believing that people are able to find their own answers and solve their own problems leads one to act in empowering ways because of the belief that people have this capacity to figure things out. On the other hand, if one believes that people need to be told what to do, or that they are not able to figure out issues on their own, it is more difficult to create conditions that are enabling. For some, it might even feel irresponsible to put people in these circumstances or to allow them to have control over these types of decisions.

Enabling and empowerment

At the time of the *Ottawa Charter*, the word ‘enabling’ was favoured, although later this tended to be replaced with the more direct and comprehensive concept of ‘empowerment’. Essentially, this meant that a prerequisite for the new approach was that individuals and communities were to directly participate in the planning and implementation of health promotion activities. The assumption was based on the notion that only by genuinely participating in the health promotion process would people be ‘enabled’ or ‘empowered’ to take control of what determined their health. However, the concept of ‘enabling’ also referred to the more general process of changing the social, economic, and environmental conditions that made it difficult for people to become empowered. There is a deep ambiguity here: it is not clear, for some commentators, whether more macro-scale action, at a policy level, also requires active participation of local communities. There is some room for an interpretation that tends to retain a traditional paternalism when it comes to healthy public policy, leaving the ‘participatory’ aspect of health promotion to the realm of ‘community action’. As will be argued throughout this chapter, health promotion is constantly at risk of sliding back into this paternalistic approach, leaving the more ‘complex’ and high-level ‘technical’ decisions to the experts. Yet, if there is a direct link between human dignity, autonomy, and equity, then *all* aspects of health promotion must integrate the fundamental perspective of participation. In fact, it is argued that the rhetoric of ‘empowerment’ often masks a continuing bureaucratic and professional dominance of the process of improving public health (Baum 2007).

A key aspect of this ambiguity can be seen when we consider the link to health inequity. Without a genuinely participatory, empowering process, it is those worst off who are left further behind as they suffer, not only a failure to affect those conditions most important to their health, but also a direct assault on their human dignity (Sennett 2003). Those who tend to manage any gains from processes that lack true participation are usually segments of the population that already have access to positions of status and the resources and capacities to take advantage of the interventions on offer. The distinction here is between a situation where already disadvantaged people are assumed to be too ignorant or incapable of participating and thus have solutions imposed on them, and a situation where people of a privileged status delegate, as equals, to

professional experts. This is not to say that a participatory process is not better for everyone, regardless of class position or status; rather, it is to emphasize that non-participatory processes have a disproportionate adverse effect on disadvantaged groups.

On the positive side, an empowering health promotion process leaves the ownership and control of a health promotion activity or programme in the hands of the community itself. This is particularly important in communities that have suffered historical social injustices and have thus been actively ‘disempowered’ (an ugly but accurate term). Allowing people to participate in a genuine way in determining not only *what* they want but *how* they want to get it is demonstrably the most effective strategy for change. It is also the *only* strategy for sustaining progress in improving health and shifting control back to the community and away from a negative dependence on bureaucratic and professional power. In this model, professionals are not demons; they are just transformed from arrogant experts into supportive servants of the will of the community.

There is in these simple terms (‘enable’ or ‘empower’) the entire, complex, and ambiguous story of health promotion. All the themes that will be touched upon in this chapter can be traced back to just what is at stake in the ostensive goal of ‘empowering’ people to take control over what determines their health.

What is the ‘health’ in health promotion?

Understanding how we conceptualize health is a key reflective step in health promotion. How we think about health largely determines the types of action we take to promote health. We see below how different historical conceptions of health still shape the contemporary health landscape and continue to sustain ambiguities in how people approach health promotion itself. In the twentieth century, due to the relative success of the sanitation approach to public health and the emergent hegemony of the germ theory of disease, an implicit biomedical definition of health as *the absence of disease* dominated, and along with it, a narrow, individual treatment focus, centred on the healthcare system, was the preferred solution. The WHO had, in 1946, introduced the *positive* definition of health as ‘a state of complete physical, mental, and social well-being and not merely the absence of disease or infirmity’ (WHO 1946). Nevertheless, this definition had little concrete impact on actual health systems, leaving the absence of disease approach to health as the default option when governments turned their attention to the public’s health.

The Lalonde Report, an official document produced by the Canadian Department of Health and Welfare (Lalonde 1974), marked a significant change in thinking about health. Although the report is recognized internationally as the first government document to suggest that health promotion could be a key strategy for improving health, its other, more significant contribution, was to redefine how we view health. Lalonde’s report argued that the healthcare system plays only a small part in determining health, and suggested that health was determined by the interplay between human biology, healthcare organization, environment, and lifestyle. This view of health became known as the ‘lifestyle or behavioural approach to health’, partly because the ‘environmental’ dimension was either ignored or treated narrowly.

With the publication of the discussion paper on concepts and principles of health promotion (WHO 1984) and the endorsement of the *Ottawa Charter for Health Promotion* (1986), a third

Table 6.4.1 From concept to action: different approaches to health

	Medical approach	Behavioural approach	Socioecological approach
Health concept	Biomedical; absence of disease or disability	Individualized; physical-functional ability, physical well-being	Positive state connectedness; ability to do things that are important or have meaning; psychological well-being
Health determinant	Disease categories, physiological risk factors (e.g. hypertension)	Behavioural risk factors (e.g. unsafe sex)	Psychological risk factors (e.g. isolation) and socioenvironmental risk conditions (e.g. poverty)
Principal strategy	Surgery, drugs, therapy, illness care, medically managed behavioural change	Advocacy for healthy lifestyle choices	Personal empowerment, small group development, community organization, coalition advocacy, political action
Programme development	Professionally managed	Negotiated with communities and professionals	Managed by community in critical dialogue with supporting professionals and agencies

view of health arose: the socioecological approach. This approach defined health as ‘a resource for everyday life, not the objective of living’. ‘Health is a positive concept emphasizing social and personal resources as well as physical capacities’ (1986, p. 1). In order to reach this state of physical, mental, and social well-being, people must be able to identify and realize their aspirations, to satisfy their needs and to change, or cope, with their environment. This inextricable link between people and their environment provides the conceptual basis for this socioecological perspective on health and it forms the conceptual base for health promotion practice.

At first glance, these different views of health may appear to be developmental or historical. However, Labonté and others (Labonté 1993; Rootman and Raeburn 1994; Raeburn and Rootman 2007) argue that, in fact, all three views of health (along with many other definitions) continue to be endorsed by different people in the field of health promotion and, furthermore, that the view of health one holds influences one’s health promotion practice. Table 6.4.1 illustrates this connection between how we think about health, our view of health, and our actions (health promotion practice). For example, if we hold a view that health is the absence of disease, we are likely to talk about disease processes and risk factors and to manage the problem professionally by prescribing a treatment. If we hold a socioecological view of health, we are more likely to focus on the conditions in which the person is living, the factors that are influencing their ability to meet their needs, and to use enabling strategies to assist the person to have more control over their health.

The Ottawa Charter strategies

The three strategies mentioned in the *Ottawa Charter* are: *to advocate*, *to enable*, and *to mediate*. We have already reflected upon the second strategy, as it is part of the definition of health promotion. However, a few words need to be said about the other two strategies.

The concept of *advocacy* receives very little elaboration in the *Ottawa Charter*. In the *Health Promotion Glossary*, it is stated that advocacy ‘can take many forms including the use of the mass media and multi-media, direct political lobbying, and community mobilization through, for example, coalitions of interest around defined issues. Health professionals have a major responsibility to act as advocates for health at all levels in society’ (WHO 1998, p. 6). This raises one of the many thorny issues that come

up when professionals are caught between highly mobilized and often highly critical communities and a state bureaucracy that is extremely reticent about providing funding that sanctions and supports the capacity for critical attention to its policies and programmes. Even at the level of independent professional organizations, the participation and funding provided by government bodies creates a tension around the organization taking strong critical perspectives. Another aspect of this strategy, as defined in the glossary and glossed over, is the potential contradiction between activities such as ‘political lobbying’ and ‘community mobilization’. Often, the same organization or individual will be less effective as a political lobbyist to the extent they are perceived to be directly associated with community mobilization efforts that the powerful are either indifferent to, or actively disfavour.

Mediation is an even more delicate strategy for health professionals. Its original *Glossary* definition in relation to health promotion was: ‘A process through which the different interests (personal, social, economic) of individuals and communities and different sectors (public and private) are reconciled in ways that promote and protect health’ (WHO 1986). In the expanded definition of 1998, more explicit emphasis is given to the potential conflicts that often arise between the competing interests mentioned in the original definition. However, the goal of mediation as ‘reconciliation’ is left unchanged. While there is nothing inherently wrong with the idea of reconciliation, professionals should be extremely self-critical and reflexive when operating with this strategy. Two dangers are apparent with the strategy. First, in striving for ‘reconciliation’, one may simply paper over a conflict for the purposes of short-term peace, while leaving the principal reasons behind the conflict intact, thereby creating the potential for longer-term embitterment and strategic action by all parties, which ultimately undermines the appearance of agreement. Second, a very real threat to equity can arise when professionals reconcile a conflict between the powerful and the powerless and end up re-enforcing the powerful at the expense of the powerless. This tendency is very strong given the fact that professionals have little to gain personally from any radical re-structuring of power relations. Despite these important caveats, mediation has become even more critical for the success of health promotion in the future, especially in relation to the new global, multilayered context of health governance that the *Bangkok Charter* (WHO 2005) has set out to address and which will be discussed later.

The Ottawa Charter action areas

The priority action areas of the *Ottawa Charter* were identified as those areas that were seen at the time of the charter (and still to this day) as critical arenas for health promotion's strategic activities. We will not try and survey the myriad accomplishments of health promotion activity; rather, consistent with our general approach, we will offer a few critical comments on each action area:

Building healthy public policy

There are three elements of healthy public policy emphasized in the *Ottawa Charter*:

1. If, as the Lalonde Report (1974) argued, the determinants of health lay mainly outside healthcare itself, then policy action must come from policy sectors other than health. The health sector would still play an important, but not exclusive, role in public policy action to support health.
2. Healthy public policy requires the coordinated use of all policy levers available, including 'legislation, fiscal measures, taxation, and organizational change' (WHO 1986).
3. Healthy public policy requires the identification and removal of obstacles to the adoption of such policies in non-health sectors.

Without going into a long list of efforts and results in this area, the progress made can be summed up as substantial and encouraging in regard to changes in the rhetoric and discourse around health, in both developed nations and in many of the global institutions responsible for improving health and development worldwide. Conversely, one can equally characterize progress as ephemeral and demoralizing when it comes to the concrete goal of 'coordinated action that leads to health, income and social policies that foster greater equity' (WHO 1986). For a variety of reasons discussed in the later subsection on the political economy of health promotion, given the increasingly urgent crisis of widening inequities in health both between and within societies, the collective policy response of the most powerful countries on earth has been miserly and despicable. To call it 'inadequate' is a gross understatement and an unconscionable euphemism.

When *action* finally starts to catch up with some of the lofty rhetoric behind the calls for 'health in all policies' (Ståhl et al. 2006), health promotion can begin to find some satisfaction in the area of building healthy public policy. Since the last version of this chapter we have seen this contradiction intensify, as the global economic crisis brought on by the 2008 financial crash has led to some very regressive shifts in fiscal policy and thus social supports for a healthy public policy; meanwhile, at the level of rhetoric, global institutions, such as the WHO, have been increasingly supportive of the conceptual logic of healthy public policy. We will discuss some of the latter recent developments in relation to the *Health in All Policies* movement in a later section.

Creating supportive environments

This area forms the basis for what is called the *socioecological* approach to health. Here it is asserted that both the natural and built environments are inextricably linked with people's health. It is crucial to understand that the conceptualization of supportive environments given here is consistent with the expanded, positive understanding of health as a 'resource for everyday life'. It is not merely about threats to physical health, but involves creating conditions that allow people to have 'living and working conditions

that are safe, stimulating, satisfying, and enjoyable'. This entails the complex relationships between rapidly changing technologies, working conditions, resource use, climate change, urbanization, and health (amongst others).

In considering progress, past endeavours, and future prospects in this area, one must take into account the lofty ambition (and some would say naïvety) of this programme of action. As a project of knowledge development, its referral to the 'complex interrelatedness' of contemporary societies is but a cipher for the entire corpus of theoretical and empirical dispute and debate within the social sciences over how to characterize what are now acknowledged to be multiple, interrelated, global, national, regional, and local processes of socioeconomic and cultural change (Held et al. 1999). Later we consider some recent moves toward adopting complexity science and systems thinking to more adequately address this complex interrelatedness.

In the real world, we are not able to coordinate all the best knowledge sources available and neatly calculate what is best for health. Instead, we are left with tools like 'health impact assessment' (HIA) (Kemmm 2006). The action area of creating supportive environments can be seen as a great boon to academic productivity, both theoretical and empirical; yet, before the final judgements of the academy can be handed down, actions must be taken and decisions must be made.

Communities and developers, politicians, and bureaucrats must decide whether to build this or that highway, license this or that mining operation, enact this or that employment regulation, and build this or that oil pipeline. We are thus forced, by the necessity to decide and act, into an inevitable reduction of complexity. The question is not whether this is a good or bad thing; it is *how*, by what *process*, is complexity reduced? Whither participation and empowerment in a field dominated by professional expertise and the cloistered secrecy of executive and administrative decision-making in both the public and private sectors?

We argue *against* the implication that instruments like HIA inevitably vitiate participatory processes (Kemmm 2006). The natural tendency is always to define ahead of time, objectively, what elements of the built or natural environment are most important for enhancing people's health. From a utilitarian perspective, locally defined needs and wishes may even legitimately be ignored in the name of some greater good for a larger population. However, health promotion should always err primarily on the side of the fundamental value of the autonomy and the dignity of people and their communities. In this mode, participation is foundational, even in what are *prima facie* obvious areas for the guidance of refined professional expertise. In enquiring into the best way to protect and enhance the built and natural environment for health, the first step is to find out what people actually identify as the things that would make life 'safe, stimulating, satisfying, and enjoyable'. From the professional perspective this route has one incontestable drawback: people are inevitably confused, ignorant, inconsistent, contradictory, and even just 'wrong'. 'People' will disagree with each other; will get annoyed or, even worse, angry; will disrespect experts, politicians, lawyers, and any number of people who 'actually know' about the issue. What is feared here is what is fondly called deliberative politics; in other words, the foundation of democratic civil society.

We are, as is universally acknowledged in the health promotion community, a long way from creating supportive environments

for health, especially for those suffering gross inequities in social conditions and in consequent health outcomes. What is less often acknowledged is that part of the reason this is so difficult is that we consistently exclude the very people we are meant to be helping from determining the goals, and strategies necessary to move from here to there. Once again, we are led to believe that the ends can justify the means; we can have non-participatory processes as long as we intend to make changes to enhance the lives of the less fortunate. That we end up in a place we did not intend, is inextricably linked to the fact that, at crucial junctures, when inevitable changes of directions and compromises are made (local development processes are a prime example), the people who have an inherent interest in speaking up for the powerless (the powerless themselves) are nowhere to be seen, or are barely heard.

Strengthening community action

This action area is at the very heart of health promotion; in fact, it can be argued that this action area is the one where the basic principles of health promotion lie. You can imagine (wrongly) participation, equity, and empowerment to be contingent add-ons to the other action areas; with strengthening community action the essential unity of all the values of health promotion are embedded as necessary features of its realization. Indeed, what we see in this area is the place where the true spirit of health promotion is anchored in community development as a process. In fact, in the *Ottawa Charter* itself, there is a strange ellipsis where the term community development is introduced in the section on strengthening community action. It is as if one missed something: there is no linking phraseology relating community development to strengthening community action. This, we surmise, is no error: strengthening community action quite simply *is* community development.

Consider the definition of community development as agreed upon at the International Association for Community Development at a meeting in Budapest in 2004. Community development is a:

way of strengthening civil society by prioritising the actions of communities, and their perspectives in the development of social, economic and environmental policy. It seeks the empowerment of local communities, taken to mean both geographical communities, communities of interest or identity and communities organizing around specific themes or policy initiatives. (Craig 2005, p. 3)

For a more sustained treatment of the need to recognize the central place processes of community development and empowerment should play in health promotion, Raeburn and Rootman's *People-Centred Health Promotion* is an essential reference (Raeburn and Rootman 1998). Raeburn and Rootman draw heavily, in their chapter on community development, on Meridith Minkler's important piece, 'Improving health through community organization' (1990). In this seminal piece, Minkler outlines the five principles she sees as foundational to community organization or development:

- ◆ Empowerment
- ◆ Community competence
- ◆ Participation
- ◆ Issue selection
- ◆ Creating 'critical consciousness'.

As is now obvious, we have run into some of these principles already, the key to which is that the community itself has collective control over the process of identifying issues and planning how to address them. In addition, the important notion of 'critical consciousness' is raised. This refers to the need for critical dialogue in the Freirian sense (Freire 1972); this is particularly important when working with historically oppressed or disadvantaged communities.

Developing personal skills

The new wave of health promotion has often downgraded attention to this critical aspect of its mandate. The *Ottawa Charter* tells us that health promotion 'supports personal and social development through providing information, education for health, and enhancing life skills'. However, since the *Ottawa Charter*, health promoters, with some exceptions, have tended to either ignore or aim strong criticism at the developing personal skills area. This has come about for three reasons. First, as part of the critique of health education, it was argued that individually focused education approaches were generally ineffective in bringing about health promoting behavioural change; instead, a switch to an emphasis on the *social* factors that influence health was necessary to overcome the limitations of traditional counselling and other interventions circumscribed by the discipline of psychology. Second, the emphasis on developing personal skills was associated with the 'victim-blaming' element that many health promoters saw as the consequence of an interpretation of the Lalonde report and other government documents (particularly, the approach taken in the United Kingdom under the Thatcher governments) in the context of the neo-liberal rolling back of the state's commitment to a strong social safety net. Finally, although developing personal skills is a central mechanism for empowering individuals to take control over their own health, many worried that, in this narrow approach, the *collective* strengthening of communities was adversely effected by too much emphasis on individual empowerment.

All of these concerns are legitimate, though in each of them there is a high risk that we will miss important opportunities by mistaking what are contingent tendencies for essential features.

As has recently been argued, the ignorance of, or even hostility to, work in this area may seriously damage health promotion's potential impact (Godin 2007). First, while many health education and behaviour change approaches are limited in their effectiveness, there are some demonstrably effective interventions that should not be ignored (Kok et al. 1997). Furthermore, we can learn and are learning about why some approaches in this area have not been effective. Second, the fact that this area of health promotion can be enlisted as part of a more general 'victim-blaming' culture of health promotion, does not mean it must be enlisted; in fact, to the extent that genuinely empowering health education is taken seriously, the resulting improvements in self-esteem should work against victim blaming. Third, individual and community empowerment should not be a zero sum trade-off. It is only when an exclusive focus on individuals is emphasized that we will have the phenomenon of rescuing survivors from a sinking ship.

In summary, while we must be vigilant against the temptation and limitations of an individually focused, skills development approach, we must also re-engage with the most advanced and progressive elements in this area of work. If we fail to do this, we will jeopardize a key aspect of health promotion.

Reorienting health services

While we have made some important gains in the previous four areas, reorienting health services has proved more difficult. In general, throughout the world, health services remain medically dominated, cure and treatment focused, and individualistic. The *Ottawa Charter* states ‘the role of the health sector must move increasingly in a health promotion direction, beyond its responsibility for providing clinical and curative services’. However, ‘across the world, there appears to have been a stubborn resistance to systematic change in healthcare services and only limited examples of effective and sustainable health services reorientation’ (Wise and Nutbeam 2007). Health services need to embrace an expanded mandate which is sensitive and respects cultural needs. This mandate should support the needs of individuals and communities for a healthier life, and open channels between the health sector and broader social, political, and physical environmental components.

Health services are broad and far-reaching, with the most complex service for health promotion being the acute care hospital setting. There has been some advancement in this area with the creation of the healthy hospital settings movement, with some research evidence that it is possible to practice from a health promotion perspective even within this particularly medically dominated environment, for nurses at least (Hills 1998). However, we want to focus in this chapter on the area where health promotion should flourish but has not as yet—primary healthcare. Many who work in health promotion would argue that the *Alma Ata Declaration* (WHO 1978) was the precursor for the *Ottawa Charter*. These two documents share the same values, principles, and basic tenets; the *Alma Ata Declaration* addresses health systems more particularly while the *Ottawa Charter* has a broader mandate. But it is their relationship that provides the key to reorienting health services. That is, primary healthcare is a place for health promotion to focus its energy in terms of reorienting health services. In fact, the more that health promotion disassociates itself from primary healthcare, the more we give the impression that it is in the domain of medicine, not health. ‘The more health promotion becomes distinct from the world of curative care, the more the latter is allowed to continue to be seen as the real work of medicine’ (MacDonald 1992).

We want to be clear that when we are talking about primary healthcare, we are not talking about primary care. These terms are often confused or used interchangeably. Primary healthcare refers to the philosophy and principles articulated in the *Alma Ata Declaration* (WHO 1978). It calls for universal access to health services (universality) and the removal of geographic, social, economic, or cultural barriers to access (accessibility); it demands community participation in planning, operation, and evaluation of health services (participation); it requires integration across health and other sectors such as housing, education, and employment; it recognizes the power of multidisciplinary teams working as equal partners for the health of the community; it focuses on a range of services, determined by the community, that include health promotion, primary prevention, rehabilitative, and curative (essentiality); and, it demands a commitment to equity concerning issues of power and resources (equity and access). Therefore, primary healthcare resists the conceptual and operational separation of treatment and prevention which fits the engineering model of healthcare, with prestige and often scarce

resources going to clinical medicine to the neglect of prevention, promotion, and rehabilitation (MacDonald 1992).

People who work in health promotion and understand its philosophy and principles must be involved in the development and implementation of primary healthcare. Many people working in health promotion are of the opinion that health promotion and healthcare are distinct and separate entities. They are critical of health promoters who talk about healthcare or health service delivery at the same time that they are talking about health promotion. We have a different opinion: it is necessary, not only to talk but to act as health promoters to facilitate primary healthcare reform.

Besides the *Ottawa Charter* outlining our responsibility to take up this challenge, there are two other reasons why it must be people who work in health promotion who participate in the reorientation of health systems to primary healthcare.

First, the health system is controlled by the powerful. There is a hegemony that supports a predominant treatment/cure paradigm. Power resides in these structures and with the health professionals who work in those systems. So, as advocates for equity and social justice, health promoters have a responsibility to take up this challenge. If we continue to work only in the community where we are comfortable, we will avoid confronting one of the greatest challenges of our times: creating a health system that is based on the principles of health promotion. We are not neutral in this process. As Paulo Freire (1972) said, ‘washing one’s hands of the conflict between the powerful and the powerless, means to side with the powerful, not to be neutral’. Kickbusch (1989) confirms this concern. She states, ‘herein lies the great historical opportunity and challenge. Maybe health promotion can break the deadlock of the health policy debate that is basically about medical care and provider dominance’ (p. 14). As she suggests, we are well beyond the burden of proof needed to claim that health promotion is successful—we have demonstrated this through our change in attitudes towards smoking, drinking, and nutrition—even if these are mainly concerns of the middle class and of high-income countries. ‘Accountability and the burden of proof should now lie with the medical system’ (Kickbusch 1989, p. 14).

The second reason that health promoters must take up this challenge can be summarized in one question: if health promoters do not advocate for primary healthcare based on the principles of the *Alma Ata Declaration* and the *Ottawa Charter*, what model of primary healthcare will dominate our countries?

Health promotion: history and influences

Health education

Health education plays a profound role in the history of health promotion. While it is true that health promotion is an ‘essentially contested concept’ claimed by a variety of different interests and actors (Green and Raeburn 1988), many of its most prolific commentators, particularly in the area of health promotion research and knowledge development, have been from the field of health education (Green and Kreuter 2005).

These writers have often been concerned with the failure of traditional health education approaches to help motivate individuals to act on health information. Following Tones, we adopt his definition of

health education as: 'Any intentional activity which is designed to achieve health or illness-related learning, that is, some permanent change in an individual's capability or disposition' (Tones 2004, p. 7). This refers to what knowledge, attitudes, or skills can be acquired by individuals through a variety of health education processes. In relation to health promotion, key health educators have radically restructured the traditional approaches to influencing health behaviour. Most of this work has revolved around challenging what are now seen to be simplistic and mechanical models of health belief and health decision-making. At the centre of this change has been an adoption of the concept of empowerment and an advocacy for using participatory learning processes that break down the power imbalances between health professionals and lay members of society. Crucially, the relationship between devolving control, developing self-esteem, and bridging the gap between knowledge, attitude, and behaviour is highlighted.

In relation to the overall theme of health equity, the move away from traditional health education models has been critical. Without the concept of empowerment, and the development of capacities and self-esteem, the traditional 'health action model' of raising awareness and changing attitudes to health behaviours tended to exacerbate health inequalities, as the 'prepared' middle classes quickly adopted the new healthy practices of more exercise, less smoking, and a healthy diet. The efforts to help population groups that had both the worst health outcomes and the most intransigent health-related social conditions have not been nearly as successful.

A detailed account of these changes can be found in Tones (2004). One very important aspect of his account is how health promoters can learn, as professionals, to overcome the social gap in both power and understanding between them and the groups and individuals they aim to enable and empower. As Tones notes, the 'holy trinity' of counselling (respect, empathy and genuineness) is pertinent here. Often the more socioecological accounts of the health promotion process gloss over this crucial interactive aspect of health promotion. Whether it is with individuals or with groups, health promoters cannot act effectively without using highly developed skills of empathic understanding and facilitation. Particularly with group interactions, where often highly charged community issues are discussed, the professionals striving for neutrality and objectivity will find themselves unable to cope with the anger and resentment felt by people who perceive a history of grave social injustice behind their 'health' problems. It is important that these basic counselling skills are imparted to health promoters-in-training before they go out into communities and work with them on issues relevant to their health.

This shift in health education from an information-giving, pamphlet distribution approach to an empowerment liberatory approach has brought renewed interest in Freire's emancipatory education paradigm (1972). Health promoters in several countries, most notably those in Brazil, have reclaimed and embraced his basic premises and have employed his dialogical problem-posing teaching strategies that help make health education more consistent with the principles and values of health promotion and the 'new' public health. Freire's (1972) model of empowerment education describes a three-stage methodology consisting of listening, participatory dialogue, and action. Freire proposes that the main strategy of empowerment education, critical dialogue, requires us to engage in a process of problem-posing rather problem-solving.

Problem-posing is different from problem-solving because it does not seek immediate solutions to problems. Rather, generative themes arising from the listening phase are 'codified' and posed as problematics to raise group consciousness about specific issues. Wallerstein and Hammes (1991) contend that this process recognizes the complexity and the time needed to create effective solutions to societal issues. 'An effective code shows a problematic situation that is many sided, familiar to participants and open-ended without solutions' (Wallerstein and Bernstein 1988, p. 383). Freire describes these as 'generative' themes because they generate energy and motivate people to act. Freire contends that, through a process of dialogue that reflects on the generative themes raised through listening, people become masters of their own thinking in interaction with others (1972, p. 95). As Wallerstein and Bernstein explain: 'The goal of group dialogue is critical thinking by posing problems in such a way as to have participants uncover root causes of their place in society—the socio-economic, political, cultural, and historical contexts of personal lives' (1988, p. 382).

Freire cautions that 'the liberating educator has to be very aware that transformation is not just a question of methods and techniques' (1972, p. 35). If that were the case, we could simply substitute one set of methods for another. 'The question is in a different relationship to knowledge and to society' (1972, p. 35).

Public health

Many health promotion researchers preface their scholarly remarks on the birth and development of health promotion with a discussion of its relationship to its older, more developed discipline, public health (Kickbusch 1986; Terris 1992). How this history is understood is perhaps the most telling aspect of how health promotion and its progress are viewed as a contemporary phenomenon. The argument developed below is that there has been a tendency within health promotion to tell a story of public health as a 'fall from grace'—a fall from its original reforming, perhaps even zealous, focus on the social and environmental causes of ill health, to a more restrictive, preventive biomedical era, and finally, to a broader scale but narrower scope in the 'lifestyles' approach focused on individual risk factors and behavioural change (Kickbusch 1986). Health promotion steps into the story to herald the era of a 'new public health', as a sort of re-emergence of the spirit of the nineteenth-century socioenvironmental model, with a modern gloss on the more subtle socioeconomic determinants of health. The purpose of this critical analysis is to challenge this tendency to nostalgia, and to explicate some of its continuing consequences for health promotion's rather schizophrenic relationship to public health. The 'golden age' of public health was influenced by a particular philosophical and political outlook that still finds its expression today in its most modern and rigorous proponents.

The history of health promotion conventionally begins with the publication of the Lalonde Report, entitled *A New Perspective on the Health of Canadians* (Lalonde 1974). The report was the first high-level national government document in the world to advocate for health promotion as a basic strategy for improving population health. It was influential internationally and set the stage for future debate with its concept of the *health field* as the articulation of the argument that the medically dominated healthcare system was only one and perhaps the least significant determinant

of health, alongside biology, the physical and social environment, and individual lifestyles. The Lalonde Report relied explicitly for its argumentation on such critiques of the healthcare system found in 'social medicine' as those comprehensively outlined by (McKeown 1976), but which had their roots in the classic public health tradition of William Petty, Johann Frank, Rudolf Virchow, and William Farr (White 1991). The report contains not only the notable tension between an emphasis on individual lifestyles and the subsequently neglected socioenvironmental factors, but also an equal tension, given its own chapter heading, of 'Science versus Health Promotion'. Here it is made very clear that the 'science base' of the health field concept is epidemiology and, in this context, health promotion is seen as that type of action that must be taken even though the pertinent scientific questions have yet to be definitively answered. In some ways, this attitude allowed some initial breathing space for health promotion to prosper; however, by setting up this dichotomy, it ensured that, eventually, when 'science' made its accounting, health promotion would have its day of reckoning with epidemiology.

Meanwhile, many in the health promotion community, especially in Europe and Canada, were starting to develop an independent conceptual basis for their work, based on a rigorous reflection on the type of actions necessary to most effectively promote the health of individuals and communities. Much of this work evolved out of a complex internal critique of the failure of traditional health education approaches and a more sophisticated understanding of behavioural change (Kickbusch 1986; Tones 1993). Yet, in some countries, such as Canada, the absence of a strong health education tradition contributed strongly to a more socioecological approach to promoting health (with some of its most influential leaders being sociologists and nurses, rather than psychologists and health educators). Furthermore, for a variety of complex reasons (including, again, individual leadership), much of the discourse of contemporary social movements (new leftist, feminist, gay/lesbian, environmentalist) found its way onto the official agenda of major institutions such as the WHO and Health and Welfare Canada (Labonté 1994). As has been recognized by one of the leaders in health promotion internationally, Canada provided a hybrid and fertile mixture of traditional welfare state values and innovative community activism that seemed to provide the perfect ground for a push for the new socioenvironmental approach to health promotion (Kickbusch 1994). Out of this productive interaction between European 'health promotion tourists' (Kickbusch 1986, 1994) and many able Canadian activist/public health practitioners, grew the idea and finally the accomplishment of the *Ottawa Charter for Health Promotion* (1986).

To fully understand the impact that the *Ottawa Charter* had and continues to have, it is important to see that there was a crucial transformation from the epidemiological and bureaucratic dominance of the Lalonde Report to the emerging 'more pluralistic (and messier) social-science paradigm of human and social relations' embedded in the *Ottawa Charter* (Labonté 1994, p. 86). This shift is key to understanding the constant tension between a 'scientific' approach to health promotion and the 'values' underlying the *Ottawa Charter* that is renewed whenever health promoters are asked to more rigorously account for their activities. It raises the uncomfortable question for those who, correctly, see the importance of reconnecting health promotion to the new public

health, of just how 'new' the new public health is willing to be, when it comes to its underlying philosophical commitments.

This same tension underlies some of the confusion within the health promotion research community about how to relate to the more recent (Evans and Stoddard 1990) emphasis on 'population health' (Labonté 1997; Poland et al. 1998; Raphael and Bryant 2002). On the one hand, there is a justified admiration for the advocates of population health for their influential arguments about socioeconomic determinants of health, even so far as to single out progressive population health researchers such as John Frank (Raphael and Bryant 2002). On the other hand, there is the well-articulated angst about the lack of health promotion principles within the population health perspective. The critiques of the population health perspective for its lack of emphasis on values, its weak or non-existent orientation to action, and its somewhat imperious attitude to what is to count as proper 'knowledge', are all cogent and well-aimed. The question is: why should this be a surprise? It is not enough to point out the baleful influence of a replacement ideology for health promotion. Where did it come from, and why is it so influential? Furthermore, is this newly emergent approach (Evans and Stoddard 1990) really so new? How far is it simply a modern, sophisticated renaissance of that very same 'golden era' of public health that health promoters so often return to as their intellectual and moral heritage?

Although health promoters themselves (especially Canadians, who were the ones facing this challenge directly) reacted strongly and were able to defend the rationale for keeping a health promotion focus, the more incisive critiques were often too 'reactionary' and came off rhetorically as overly defensive. A more accommodating response came from within Health Canada itself with Hamilton and Bhatti (1996) introducing the concept of *population health promotion*. This was clearly an attempt to marry these two potentially adversarial positions and to cement the term health promotion as an integral component of population health that could not be ignored.

Why is it that health promotion often seems 'behind the game' in the science debate? Partly, this is due to the fact that, as Labonté says and a *Companion to Social Theory* attests (Turner 2000), the social science world is 'messy'. However, it may also be partially true that, for too long, health promotion has neglected its need to develop an independent 'science base' having unconsciously bought into that original Lalonde dichotomy. This is becoming increasingly clearer as many of the leading proponents in the field are pushing for more intensive theoretical development, a pressure that has become especially acute as the need for demonstrating effectiveness has increased (McQueen 2001; McQueen and Jones 2007; McQueen and Kickbusch 2007). To understand why health promotion has such a complex and ambiguous relationship to public health, it is necessary to dig more deeply into the foundations of modern public health and to unpack its driving philosophy and world view.

Politics and philosophy in public health and epidemiology

It is crucial to understand that the roots of the modern public health epidemiologists' focus on individual risk factors and randomized controlled trials (RCTs) is not in contradiction with or a deviation from the Edwin Chadwicks, the John Simons, and the John Snows of the classical public health. Rather, the full flowering

of a utilitarian calculus, an uncompromising economism, and an obdurate scepticism of anything but positivistic scientific knowledge, can be seen as the late fruit of more than three centuries of development in public health and epidemiology.

There is a dilemma and *prima facie* paradox that health promotion faces when confronting its genealogy in the history of public health. In terms of lives saved and healthy years lived, the early public health interventions to combat the spread of deadly and debilitating communicable diseases cannot be underestimated. However, it is no accident that once the environmental risk factors of the major communicable diseases were effectively neutralized, a shift in focus took place to providing preventive, immunization measures. As Kerr White (1991) so convincingly puts it, the history of public health and epidemiology can be read as successive and iterative 'redefinings of the unacceptable'. Public health has always been concerned with an economistic and utilitarian approach to the health of the population; when things start to 'cost too much', the unacceptable becomes miraculously 'visible'. To understand this history, one has to ignore the facile disciplinary chasm between public health and economics, which has only recently and tentatively been bridged (Evans et al. 1994). While economics became progressively theoretical and mathematical, public health continued the original classical liberal tradition of reformist, practical utilitarianism, most powerfully apparent in the Benthamite tradition's attempt to rationalize government and public services. There is a great irony that the humanitarian idealism (an idealism at the core of health promotion's values base) of the British 'public health doctors', such as Haygarth, Heysham, Thackrah, Baker, and Millar, was never the driving force behind concentrated public health action (Fraser 1973).

As we will discuss in the subsection on health promotion and social justice, public health shares with economics a default, often merely implicit, utilitarian ethics. This shared history is seldom acknowledged, but it is a history that health promotion must confront explicitly. Fortunately, and ironically, recent developments in public health have brought into question the utilitarian approach, finding it inadequate, particularly in relation to the question of health inequity (Anand et al. 2004). The argument fleshed out below is that health promotion must forcefully engage in helping public health move in the direction advocated for by Amartya Sen and others (Anand et al. 2004).

Social movements

In this section, we briefly review one of the constitutive ambiguities at the heart of health promotion—many public health practitioners in the 1970s and early 1980s were increasingly cognizant of the lack of participatory involvement of the 'public' in public health programming.

A strong feature of the so-called 'new social movements' in the post-1968 period was a trenchant critique of bureaucratic structures and an increasingly administered society alongside the traditional leftist critique of capitalism. Some public health institutions, particularly urban public health units, decided to transform local public health practice by integrating a participatory model of programming that was heavily influenced by this anti-bureaucratic critique (Labonté 1994). However, as Dupéré et al. (2007) argue, despite its ambitions, health promotion is still not accurately described as a 'social movement', but rather a 'professional movement that had successfully advanced a

discourse about health and the production of health'. Yet, despite this acknowledged status, health promoters have recognized that much of their effectiveness depends on very high levels of social engagement. The more recent emphasis on health in the context of globalization (Labonté 2007) makes the necessity for health promotion to engage with larger social movements, particularly on the global development agenda, even more apparent.

Nevertheless, we find health promotion once again suspended between its constitutive desire to become one with the 'community' and its real position as a mediating professional fraction, often acting on behalf of formal public institutions. In the future, health promotion will have to sacrifice some of its cherished professional neutrality to choose sides, especially in its responsibility to advocate for health. While this new form of activist engagement must be balanced with the legitimacy attained from professional status, the balance must shift quite radically, given the growing threats to health represented by the inequity of contemporary societies in a globalized world.

Health promotion, health inequities, and social justice

We have, throughout this chapter, alluded to the commitment health promotion has to the principle of health equity. This is a fundamental and central value for health promoters and is often the touchstone for deciding why, where, and how to enact health promoting practice and policy. Yet, despite this nearly constant refrain, there is still confusion within health promotion about the theoretical and conceptual basis for its concern with health equity. While most, if not all health promoters, would see health equity as a basic goal of health promotion, seldom is the specific normative dimension that underlies this commitment fleshed out. The basic understanding is that health inequities are undesirable and should be eliminated because they are a set of systematic inequalities in health outcomes that are based on *unjust* inequalities of access to resources that provide for health. The *Health Promotion Glossary* describes what equity in health entails: 'That all people have an equal opportunity to develop and maintain their health, through fair and just access to resources for health.'

However, this definition begs many key questions, such as: what is 'fair' and 'just' access? And, what are 'resources for health'? While health promoters have often reflected deeply on health inequity, much of the appeal has been to an intuitive basis for supporting the elimination of inequity. We argue that this stance is no longer good enough. Health promotion must fully engage with recent work in political philosophy, particularly in the arguments surrounding the concept of social justice that have been developing since the publication of John Rawls' *A Theory of Justice* (1971). Since Rawls' groundbreaking work, an ongoing debate has taken place concerning what is the proper approach to justice for whole societies (Kymlicka 1990; Avenari and de-Shalit 1992). More recently this debate has been expanded to consider how we are to think of justice in the global context (Nussbaum 2006). Health promoters should pay close attention to what is at stake in these debates for two reasons.

First, without an awareness of these important arguments, health promotion is liable to accept a default utilitarianism that it inherits from public health, which in turn the latter shares with orthodox economics. It is argued here that this unacknowledged utilitarianism is in direct contradiction to two profound moral

intuitions that form the core of health promotion values: that it is wrong to increase overall health at the expense of the least well off; and, that human dignity and personal autonomy are overriding values.

Second, important developments in these debates are directly relevant to concerns with acting on the social determinants of health. Recent arguments have been refined concerning why and how we should address the issue of health inequity, both within and between societies (Anand et al. 2004; Nussbaum 2000). As health promoters, charged with the responsibility to advocate, enable, and mediate for equity in health, we should be armed with the very best arguments supporting our position.

We argue here that the one of the most promising theoretical developments in political philosophy that have implications for health promotion are in the evolving 'capabilities' approach to social justice and equity (Nussbaum and Sen 1993; Nussbaum 2000, 2006). This approach most nearly matches the health promotion approach to health as a 'resource for everyday living'; according to this doctrine, the 'social bases for health' would count as a primary good, or capability that should, by right, be provided to all citizens (and by extension, all human beings) at a minimum standard (Nussbaum 2006). It cannot be assumed that arguments for equity in health are unassailable and intuitively obvious for two reasons. First, without some substance behind what is meant by equity and what kinds of resources are to be distributed equitably, the demand for equity in health can be dismissed as either empty or naïvely utopian. Second, differing conceptions of what is just will lead to different outcomes in terms of actions to promote health. For example, unless we are very clear, 'equal opportunity' can be understood in an absolute minimalist sense and can allow powerful institutions to continue to support vast inequities in resources for everyday living. As we will see below, how we conceive of social justice has a profound impact on the types of actions we can imagine as solutions to the gross inequities in health we find across the world. Specifically, it has become apparent that the goals of health promotion are intimately related to the goals of a socially just global development agenda. Next we focus on an important element that tends to be lost in much of the discourse on health equity: what are the political, economic and social mechanisms by which the social determinants of health are reproduced as unequal resources for health? This is followed by considering one emerging global initiative aimed at policy solutions in this area: the *Health in All Policies* agenda.

The political economy of health promotion

Much good work has been done on the 'political economy of health' (the analysis of how different politico-economic social structures affect health outcomes), yet an enormous amount is still required (Navarro and Shi 2001; Navarro 2002; Langille 2003; Raphael 2003). Furthermore, there have been some excellent analyses of the 'political economy of healthcare' (the analysis of the effect of different political and economic arrangements on the quality and differential access to health services). In this subsection, we outline a different question: what is it about our contemporary political and economic structures that vitiates against the implementation of health promotion strategies and actions as they are conceived in the *Ottawa Charter*?

To begin to answer this question, we need to consider the three fundamental dimensions to health promotion: empowering

communities and individuals, building health public policy, and creating supportive environments.

As has already been argued, empowerment is a key dimension of health promotion. By its very nature, empowerment aims to rebalance existing power arrangements by enabling those currently without power to gain access to the resources necessary to live fulfilled and happy lives. In order to do this with any success, health promoters must do two things: they must have a clear-headed view of existing power structures and relations; and, they must recognize, as professionals, how they themselves fit into those power relations and how they help, often unconsciously, to reproduce them. One way of seriously addressing this issue is to pay more attention to the concepts of class and status mentioned on the section on social justice and health promotion.

Health promotion, to be successful, must rely on concerted action by governments around the world, both within their own territories and in cooperation to address needs that require global action, such as on climate change. However, while these wishes are often articulated (WHO 2005), seldom are we offered an analysis of the structure and dynamics of the contemporary state system in a global context. A more reflective perspective is important here, as theorists of the state argue that certain issues and certain groups, using specific strategies, are more or less likely to be successful changing the nature of hegemonic projects and reversing the direction of state policies (Jessop 2002). Health promotion must become more strategic in how it operates vis-à-vis the state; it must recognize in an explicit way the limitations and opportunities available and integrate theoretical perspectives and practical actions in regard to one of its key areas: building health public policy.

Finally, creating a supportive environment is even more wrapped up in the dynamics of global capitalism than all the other areas combined. The fundamental prerequisites for health as outlined in the *Ottawa Charter* are: peace, shelter, education, food, income, a stable ecosystem, sustainable resources, social justice, and equity. These are the elements that, when in adequate supply, make up many of the properties of a supportive environment for health. Yet, each of these elements is in large part determined by the particular structure and dynamics of our global socioeconomic system.

It is necessary to develop an awareness of the fundamental political and economic drivers behind the dynamics of contemporary societies in both the developed and developing worlds. If equity in health relies on the fundamental fairness of social, political, and economic institutions, then ignoring these basic realities is no longer an option for a serious approach to health promotion. These important insights should no longer be gained in an ad hoc way but should be seen as part of what should constitute core knowledge for competent health promoters.

Social theory and health promotion

Recently, particularly following the report of the WHO Commission on Social Determinants of Health (2008), there has been a raft of activity by both academia and governments aimed at developing knowledge about the social determinants of health. There has also been a marked (and needed) shift of emphasis to what types of *action* societies need to take to address the consequences of the iniquitous distribution of resources that support health. Less prominent are attempts to confront theoretically the

main causal mechanisms that produce and reproduce the social inequalities that lead to health inequities. While there have been recent attempts by some health promotion researchers to re-engage with fundamental debates in social theory (McQueen et al. 2007), for the most part the public health community as a whole, and health promotion by proxy, is still dominated by the narrowly focused methodological lens of epidemiological science. This failure to confront the ghost of social theory's past is most apparent in the way that the categories of *class* and *status* are dealt with in health promotion and public health discourse. Where they are mentioned at all, they tend to be conceptualized as epidemiological variables that measure an individual or group's socioeconomic attributes or properties (e.g. income, education level, wealth, job status), not as social processes that reproduce structural disadvantages for most and accumulate power and privilege for a few (see Scambler (2012) for an excellent review of this problem). The key elements of social theory that should be at the forefront of debate in health promotion circles are considered more extensively in two recent sources (McQueen et al. 2007; Carroll 2012).

The Health in All Policies Movement

Launched as Finland's main theme of its 2006 European Presidency, *Health in All Policies* (HiAP) is a strategy to help link health and other policy sectors in an over-arching intersectoral approach to improving health and well-being and reducing health inequity (Ståhl et al. 2006). It is an attempt to reinvigorate the original emphasis in the *Ottawa Charter* on healthy public policy, and to follow up on the work done at the WHO conference in Adelaide, Australia in 1988 (WHO, 1988). Since that meeting, there has been much reflection on both the details of how to implement healthy public policy and the particular challenges posed by integrated, coherent, intersectoral action for health. More recently, the WHO reconvened in Adelaide to produce an international statement on HiAP called the 'Adelaide statement on health in all policies: moving toward a shared governance for health and well-being' (WHO, 2010). It is no coincidence that it lays heavy emphasis on 'governance'. This was followed by two important publications in 2012, also focusing on governance (Kickbusch and Gleicher 2012; McQueen et al. 2012). The central challenge of implementing HiAP has been the difficulty of managing the governance and accountability structures necessary to sustain both vertical (levels of government, non-governmental and private sector) and horizontal (cross-ministry, inter-departmental) intersectoral collaboration. We are only now beginning in public health and health promotion circles to appreciate the different type of knowledge base required to assess the effectiveness of policy implementation. We are still largely stuck in an outmoded attempt to squeeze what are really matters for political science, economic sociology and the sociology of the state into the narrow methodological confines of standard epidemiological research designs. Some emerging work (Lawless et al. 2012; Carroll et al. 2013) examines case studies of HiAP in order to better understand the key mechanisms underlying success and failure, but this is in its infancy. Clearly, HiAP is required to move forward on the intersectoral action agenda outlined in the *Ottawa Charter*; however, there is a large knowledge gap concerning implementation and sustainability that needs to be addressed in the future.

Since the last version of this chapter, little has changed in the field that might signify a shift in this direction. Training in health

promotion still lacks any real engagement with scholarly debates in the social science disciplines that have insight into these key problems.

Complexity, context, and causality in health promotion research

Over the past 15 years, a series of publications have charted the specific methodological challenges for evaluating the effectiveness of health promotion interventions (IUHPE 1999; Rootman et al. 2001; Zaza et al. 2005; McQueen and Jones 2007). There has been some scepticism about applying the methodological protocols of evidence-based medicine (EBM) and RCTs as the gold standard because of the problems of complexity and context (McQueen 2007). One emerging alternative has been to use different methods for synthesizing evidence, such as the realist (Pawson et al. 2005) or meta-narrative (Greenhalgh et al. 2005) review approaches. A more detailed treatment of these latter approaches is beyond the scope of this chapter; however, one further potential for advancing beyond traditional EBM-type methods, is in the use of so-called 'systems thinking' or 'complexity science' to understand the rich complexity and contextual subtlety of the settings within which health promotion interventions take place, and of the interventions themselves.

Key to understanding the critique of EBM and some of the proposed alternative strategies is the different nature of how causality is conceptualized. The realist alternative has a direct, philosophical critique of the underlying empiricist-positivism of EBM's approach to causality (Bhaskar 2008). Conversely, systems thinking and complexity science approaches are more concerned with EBM's inability to take account of the interactive, emergent, and non-linear dynamics of causation that are crucial to understanding health promotion interventions as complex adaptive systems that intervene in the context of settings that are themselves complex adaptive systems.

Some health promotion researchers have started to take seriously the potential for a complexity or systems approach to health promotion interventions (Rickles et al. 2007; Shiell et al. 2008; Hawe et al. 2009; Trickett et al. 2011). These emergent attempts to apply complexity science have yet to show fruit (though systems thinking in public health has a longer pedigree), yet they hold much potential to transcend the current impasses in health promotion effectiveness research.

The role of social media

Finally, an important emerging issue, and one that has attracted much attention, is the potential role of social media in public health. The pervasive use and influence of the Internet and social media in nearly all parts of the world, presents new opportunities and challenges for health promotion and health education (see Chapter 4.3). A key feature that differentiates social media from more traditional communication processes is its interactive nature, where communications are not a one-way process, and where users also play an active role. This allows the formation of new online communities, which can enable virtual participation and collaboration among its members.

In this way, social media can provide resources as well as social support for patients with specific diseases or individuals with specific needs. In view of this, social media is emerging as a key

platform for the dissemination of preventive health information. This can provide additional scientific information for individuals and communities, which can facilitate and enable greater public participation in the discussion about how the evidence base could be best used for the community. However, there are risks too that social media platforms could be used as avenues of persuasion by industry and other players who have vested interests in promulgating specific points of view.

Nevertheless, social media can also be used as a tool to listen to a much wider range of individuals and groups within the community and internationally. This can provide very useful inputs that could balance the traditional, more top-down, nature of public health programming. As a corollary, social media provides a major platform for health advocacy and activism that could lead to the strengthening of community action, the transformation of personal skills, and draw attention to health issues arising from social inequalities.

Conclusion

We have chosen not to give a technical survey of the health promotion field for which there are many excellent sources available (Tones and Green 2004; Green and Kreuter 2005). Two global perspectives on health promotion have been published, covering substantive areas and technical research problems concerning health promotion effectiveness (McQueen and Jones 2007).

Instead, we have attempted to offer the reader a chance to reflect on a set of core conceptual issues that underlie the health promotion problematic. The five key messages we want to impart about health promotion are listed here:

- ◆ Health promotion is a complex, often ambiguous concept and set of practices. Health promotion finds its core values and principles in the Ottawa Charter which bears careful examination to comprehend the essence of health promotion.
- ◆ Health promotion has an intimate connection to health education, with many of its most important and prolific thinkers having a health education background. The revolution in health education practice is directly connected to the birth of health promotion but beyond this, health promotion has its roots in the deep history of public health and has been invigorated by contemporary social movements.
- ◆ Health promotion is fundamentally about ethics, values, and social justice. Only secondarily is it about technical strategies for behaviour change. The foundational principles of health promotion are *equity, participation, and empowerment*.
- ◆ Health promotion is a professionally dominated movement. This requires health promotion professionals to be critical and reflexive in their practice; they must acknowledge power imbalances that favour professional dominance and work to restore power to individuals and communities.
- ◆ Health promotion must take its duty to enable people to control the determinants of their health seriously. To do this it must engage more directly with contemporary arguments in political philosophy and it must be aware of the dynamics of the global political economy and its effect on the potential for health promotion.

Some of these issues are well known, such as the problem of professional dominance; while others, such as the political economy of health promotion, or the engagement with political philosophy, are not addressed or require much deeper reflection.

We have argued that, at its heart, health promotion is about a radical shift in values for public health. It is not that public health was never concerned with equality or alleviating the misery of the poor; arguably, the so-called 'golden age' was driven by exactly these moral questions. However, these intuitive commitments were not sufficiently followed through when it came to not just *what* outcomes to change but *how* to change them. Too much of public health, for too long, was driven by a benevolent paternalism that, particularly when it came to dealing with chronic diseases and with vulnerable populations, ended up being counterproductive. Indeed, not only was this paternalism ineffective in many areas, it was unethical. It assumed the authority of experts and professionals, not only to determine technical solutions, but to determine needs. If we are to take the concepts of equity and empowerment seriously, they have profound implications for how we do public health interventions. We have learned that by addressing needs without first establishing a participatory framework that enables individuals and communities to determine those needs for themselves, we fatally undermine one of the most crucial capacities for health: human dignity and self-respect. This is particularly so in communities that have suffered historical social injustices. As Richard Sennett says, people subjected to this disempowering process, experience 'that peculiar lack of respect which consists of not being seen, not being accounted as full human beings' (Sennett 2003, pp. 12–13).

We hope to have demonstrated that there are many barriers to realizing this change in power relations; yet, there are also very important opportunities, such as with the Millennium Development Goals and the Commission on the Social Determinants of Health, where there is an increasing clamour for action to redress health inequities through empowering processes. It is notable that even the World Bank, often the subject of brutal criticism for exacerbating inequalities (Stiglitz 2003), has made significant moves toward recognizing the importance of reducing inequity in human development and has integrated an empowerment approach (World Bank 2006). It remains to be seen whether these gains can be translated into major policy changes and effective implementation; nevertheless, it is at this level where health promoters and all public health practitioners and researchers must have a strong advocacy position.

We hope that it is apparent that, in our interpretation, health promotion is much more than a set of technical public health interventions aimed at revamping traditional health education for the twenty-first century. We cannot let go of the core competencies built up by health education and other contributing fields, but we cannot be limited in our vision either. Health promotion has to face up to the fact that, while it may only be a junior partner in the global struggle to develop a more just and equitable world, when it comes to a key human capability and resource, *health*, it must take a lead role in making the argument for equity, develop and present the evidence for what *action* is necessary to achieve equity in health, and finally, to hold the powerful accountable where they fail to live up to the demands of justice for health. Embedded in health promotion is an imperative to act ethically and justly. In this case, unlike most, there is no choice.

Development and evaluation of complex multicomponent interventions in public health

Rona Campbell and Chris Bonell

Introduction to development and evaluation of complex multicomponent interventions

The need for a better evidence base in public health to support decision-making in policy and practice has been acknowledged by government, policy bodies, and researchers (UK Clinical Research Collaboration 2008; House of Commons Health Committee 2009; House of Lords Science and Technology Sub-Committee 2011; Katikireddi et al. 2011) and recent funding initiatives in the United Kingdom have been specifically designed to enhance the quality and quantity of research in public health and to support research capacity development (UK Clinical Research Collaboration 2013; National Institute for Health Research School for Public Health Research (n.d.)). A number of consistent themes have emerged. First is a concern that when new public health initiatives are introduced little thought is given to evaluation. The result is that opportunities for baseline data collection, the identification of suitable control conditions, and the possibility of randomizing to intervention and control conditions are missed. A second is that new initiatives and policy interventions are introduced in too rushed a way with little time for development, piloting, fine tuning, and bedding in before they are replaced by something else. A third theme is the need for researchers and practitioners to work together more closely in order to integrate evaluations from the outset so that the evidence base of what works in public health is built and can inform decisions about policy, practice, and resource allocation at local, national, and international levels. In this chapter, we consider how these concerns can be addressed as we describe methods for developing and evaluating complex public health interventions. We begin by examining what complexity means in the context of public health.

Definition and scope of the concept of a 'complex intervention'

A complex intervention is generally held to comprise a number of synergistic interrelated components where effects cannot be attributed to a single 'active ingredient' (Medical Research Council 2000). Updated guidance provided by the UK's Medical

Research Council (MRC) further suggests that complexity derives from: the number and difficulty of behaviours required by those delivering or receiving the intervention, the number of groups or organizational levels targeted by the intervention, the number and variability of outcomes, and the degree of flexibility or tailoring of the intervention permitted (Craig et al. 2008). By contrast, a simple intervention tends to be characterized as involving a straightforward pathway from the single component intervention, such as a drug treatment, to the intended outcome (Petticrew 2011). According to this distinction between simple and complex, many public health interventions and programmes are complex, although arguably vaccination programmes and some screening programmes (e.g. for phenylketonuria in the newborn) could be considered simple interventions. Recently, however, it has been suggested that the issue of complexity is not necessarily to do with the intervention but is about both the complexity of the settings (e.g. family, school, community, country) in which interventions are implemented and whether the research question being examined by evaluators of the intervention requires a simple (e.g. 'does this work?') or a complex answer (e.g. 'for whom does this work and under what circumstances?') (Petticrew 2011).

Complex interventions or complex settings, contexts, or systems

Interventions with a number of interrelated parts, it has been suggested, may be more helpfully thought of as complicated rather than complex. Complexity, so the argument runs, is a property of the system that an intervention is trying to change, not an inherent feature of the intervention itself (Shiell et al. 2008). Complex systems are said to be 'built up from very large numbers of mutually interacting subunits (that are often composites themselves) whose repeated interactions result in rich, collective behaviour that feeds back into the behaviour of the individual parts' (Ricklefs et al. 2007, p. 933). For example, Project Northland in the United States used schools as a setting for a health promotion intervention to discourage alcohol use by young people. It involved making changes to elements of the school curriculum, changing the school environment, and engagement with parents and the wider community to restrict both access to and demand for alcohol (Perry et al. 2002). The intervention is clearly a complicated one,

but is also complex. Schools were not simply the context for the delivery of this intervention but comprised a complex system, involving a whole series of different types of subunits (e.g. students, teaching staff, classes, buildings), which the intervention aimed to transform. The schools were also part of a wider community, another complex system, on which the intervention was also intended to have an impact. The intention was that the action in both systems would be mutually reinforcing and produce a reduction in alcohol use.

When developing a public health intervention, it can be instructive to understand something of the nature of complex systems, and to think of an intervention as something that is intended to disrupt the system. Doing so can help ensure that the likely mechanisms for achieving change, the potential consequences of disrupting the system (both intentional and unintentional), and the interaction between the intervention and the context in which it is being implemented, are all carefully considered from the outset.

Standardized or flexible interventions?

When the UK MRC first published a framework for the development and evaluation of complex interventions (MRC 2000) it adapted the phases undertaken in drug development and testing and proposed a five-stage schema comprising: (1) 'pre-clinical' theoretical phase; (2) phase I—modelling: defining the components of the intervention; (3) phase II—exploratory trial: defining the trial and intervention design; (4) phase III—definitive randomized controlled trial (RCT); (5) phase IV—long-term implementation (Campbell et al. 2000). Phase II was specified as the stage at which the intervention could be adapted and changed but it was made clear that 'once the RCT has begun, the intervention must not evolve, as the RCT results will be unusable if later participants experience a different intervention than earlier ones. Fidelity to treatment protocols or quality standards may be essential to effectiveness. Monitoring will be essential to ensuring that individual styles and evolution in treatment do not render results from different groups of participants incomparable or excessively reduce the effectiveness of the intervention' (MRC 2000, p. 11). This emphasis on testing a standardized intervention, implemented with a high degree of fidelity, caused some concern because, it was thought, some public health interventions might be maximally effective if they actively encouraged appropriate tailoring to local circumstances. Such a view led some to conclude that randomized trials were therefore not a suitable method for evaluating public health and health promotion interventions (McNulty et al. 2014). As Hawe and colleagues (Hawe et al. 2004) pointed out, however, this concern was based on a misconception of what is standardized. She argued that what should be standardized is the function of the intervention and the steps in the process by which change is to be achieved, not that all the components of an intervention have to be delivered in exactly the same way to each person, or in each setting. Hawe and colleagues did not reject the randomized trial as a method of evaluation but argued that 'instead of mimicking trial phases which assume that the "best" or the "ideal" comes from the laboratory and gets progressively compromised in real world applications, community trial design would start by trying to understand communities themselves as complex systems and how the health problem or phenomena of interest is recurrently produced by that system' (Hawe et al. 2004, p. 1562). However, it is an empirical question rather than a matter of principle whether

standardized or adapted interventions are more effective, and one which will depend on the intervention. This matter is discussed in further detail in the later subsection on fidelity.

Simple or complex research questions

As already mentioned, evaluations can address simple or complex questions (Petticrew 2011). For example, you might wish to evaluate the effectiveness of a multicomponent programme to reduce childhood obesity in a local authority area which includes: a health promotion intervention for pregnant women to encourage breastfeeding and healthy weaning; work with nursery schools, child minders, and day care providers to ensure provision of healthy food and sufficient opportunity for physical activity; a classroom-based intervention for primary schools aimed at teaching children about good nutrition and being physically active which also involves parents; and a health promotion intervention via large, local spectator sports clubs to encourage fathers to be physically active with their children and to eat healthily. As the commissioner of the programme, you may simply wish to know whether or not it has been effective in reducing the percentage of children who are obese or overweight and that the investment was worthwhile. Or you may wish to know: for which subpopulations of children and in what settings it was effective or ineffective; whether there were important secondary outcomes such as a reduction in obesity in adults or an improvement in educational attainment in the children; whether there were intervention synergies or feedback loops which made it more effective than it might otherwise have been; or whether there were externalities (changes outside the system but of interest) such as a reduction in the number of fast food outlets in the locality due to a drop in demand, or tipping points where, for example, increased pressure from parents and local community groups to provide better outdoor play facilities for children resulted in the local authority upgrading play parks resulting in them being more heavily used by families.

Intervening at different levels to improve the health of populations

The importance of multilevel and multifaceted interventions was set out in both the 1986 *Ottawa Charter for Health Promotion* (Rickles et al. 2007) and the later *Bangkok Charter* (Anonymous 2006) so that interventions aim both to address individual, 'downstream' determinants of health such as knowledge and attitudes, as well as community and societal 'upstream' determinants, such as access to health benefiting and health harming goods and services and social inequalities in wealth and power. When designing complex public health interventions, the socioecological approach to public health described by McLeroy and colleagues (Kenneth et al. 1988) but with its origins in the work of Bronfenbrenner (1974) on ecological systems theory, can provide a useful framework for thinking about the different levels of intervention. This socioecological framework was designed to focus attention on both social and environmental factors as targets for health promotion. It identifies five complementary levels of change, targets and approaches which are set out in Table 6.5.1.

Historical evidence suggests that the greatest improvements in public health have been achieved through non-medical interventions, such as improved sanitation, welfare benefits,

Table 6.5.1 Socioecological framework

Level of change	Target	Approach
Intrapersonal	Individuals	Changing individuals by changing their knowledge, attitudes, values, motives, skills and behaviour
Interpersonal	Small groups such as the family, work colleagues, friendship groups	Achieving change through formal and informal social networks and peer groups by changing group norms or the group culture
Institutional	Organizational settings such as schools, colleges, and workplaces	Achieving change via organizational policies and rules, and by creating healthier organizational cultures and environments
Communities as mediating structures, relationships amongst organizations and as geographical entities with political power	Neighbourhoods, community organizations	Achieving change through collective action by working with community organizations that are sources of social capital, coordination and coalition building between organizations, and increasing the representation of disadvantaged population groups on community decision-making bodies
Public policy	Whole populations at local, regional, national, and international level	Achieving structural change through the development and implementation of health promoting local-, regional-, country-, and international-level policy and legislation

Adapted with permission from McLeroy, K.R. et al., An Ecological Perspective on Health Promotion Programs, *Health Education Quarterly*, Volume 15, Issue, pp. 351–77, Copyright © 1988 by Society for Public Health Education, DOI: 10.1177/109019818801500401.

and improved workplace safety (McKeown 1976). Current evidence also indicates that multifaceted and multilevel interventions are more effective than those operating at a single level (Greaves et al. 2011), and that environmental level interventions are more likely to be cost-effective than individually targeted clinical or non-clinical prevention interventions (Chokshi and Farley 2012). Recent reviews of the use of socioecological models in health promotion since the late 1980s have, however, suggested that published evaluations still tend to focus on one or two levels of intervention (Richard et al. 2011; Golden and Earp 2012), although there has been a notable increase, particularly in the last few years, in interventions with multiple and more ‘upstream’ targets, such as the community or political environment (Richard et al. 2011).

Health inequalities

Public health has the dual goals of improving population health and reducing health inequalities. One approach is to target interventions at disadvantaged groups or those at high risk of morbidity or mortality. This can be problematic, both because it can sometimes be stigmatizing and even harmful, but also because even if effective in reducing these groups’ risk it may be insufficient to bring about substantial population-level reductions in risk because, as Geoffrey Rose pointed out (Rose 1981), where disease risks follow a bell-shaped curve (as is the case with almost all non-communicable disease), the majority of cases of a disease will arise from those at low or medium risk (because there are simply more of them). However, universalist approaches which do not address the ‘upstream’ determinants of disease and only address individual behaviour may have the potential for widening inequalities because of the ‘inverse prevention law’ (Gordon et al. 1999) whereby socioeconomically advantaged groups are able to benefit disproportionately from universal interventions. Progressive universalism has been advocated, for example, by the *Marmot Review*, as a way of avoiding these difficulties by ensuring that action on health inequalities both addresses ‘the causes of the causes’ but also by ensuring that the scale and intensity of

more downstream interventions are proportionate to the level of disadvantage (Marmot 2010).

These matters must be examined empirically within evaluations. A recent evaluation of the free swimming initiative for children, introduced in England as part of an intended legacy of the 2012 Olympic Games, is a good example of an evaluation examining whether the inverse prevention law was operating. The findings indicated that uptake was not socioeconomically stratified but was higher among girls and older children. The authors concluded that by ending the initiative after two years, an opportunity had been lost to promote physical activity across the social gradient (Audrey et al. 2012).

When developing public health interventions, it is therefore important to consider their potential for narrowing or widening health inequalities, and to ensure that evaluations formally test whether factors such as socioeconomic status, gender, or ethnicity moderate (statistically interact with) intervention effects. The PROGRESS acronym (Evans and Brown 2003) indicates disadvantage may be related to place of residence, race/ethnicity, occupation, gender, religion, education, socioeconomic status, and social capital and is a helpful prompt to thinking about which factors are relevant to the population for which the intervention is being designed.

Stages in the development of complex interventions

Review of existing quantitative and qualitative evidence

The first practical step in developing a complex intervention, whether designing something new or modifying an existing approach, is to review the available evidence. If there are already relevant systematic reviews, then it may only be necessary to read these or update them. But if not, you may need to conduct your own review (see Chapter 5.15 for further information about systematic reviews). While quantitative systematic reviews will tell

you what is known about the effectiveness of a particular intervention, it is also useful to review relevant qualitative research which may provide important knowledge about the likely acceptability of your proposed intervention and identify potential barriers and facilitators to implementation. It will also be useful to learn about risk and protective factors, both 'downstream' and 'upstream' for the outcome of interest, again preferably drawing on systematic reviews, to consider if existing interventions are comprehensive in addressing these.

Involving policy and practice partners from the outset

Consulting or collaborating with key stakeholders at this early stage will also provide useful insights into exactly what is seen to be required from the policy and practice perspective. Involving stakeholders from the outset is also more likely to result in its successful translation from research into routine practice if the subsequent evaluation of the intervention shows it to be effective and cost-effective (see Chapter 6.1 for details of social science research methods including interviews and focus groups).

Public involvement from the outset

Similarly, working directly with those whose health it is hoped will be improved by the planned intervention is also vital in ensuring that it is relevant and acceptable. In the health and social care sectors, pre-existing groups represent particular patient and client groups, which can be engaged as partners in research. In public health, identifying representative groups, particularly for universalist interventions, may be more challenging. There is, however, guidance available on how to approach this and examples of good practice. INVOLVE is part of the National Institute for Health Research in the United Kingdom and its role is to encourage and support increased public involvement in health research (INVOLVE 2012) and its website provides ample guidance for researchers (<http://www.invo.org.uk>) and the public. Involvement in public health research can and should include specific population groups such as children and young people (Bird et al. 2013) and there are specialist groups being set up who can provide such input. The ALPHA group (Advice Leading to Public Health Advancement) is one such example. This specially trained group of young people meets monthly to provide input into research undertaken by the DECIPHer public health research centre and other research organizations (DECIPHer n.d.).

Importance of theory

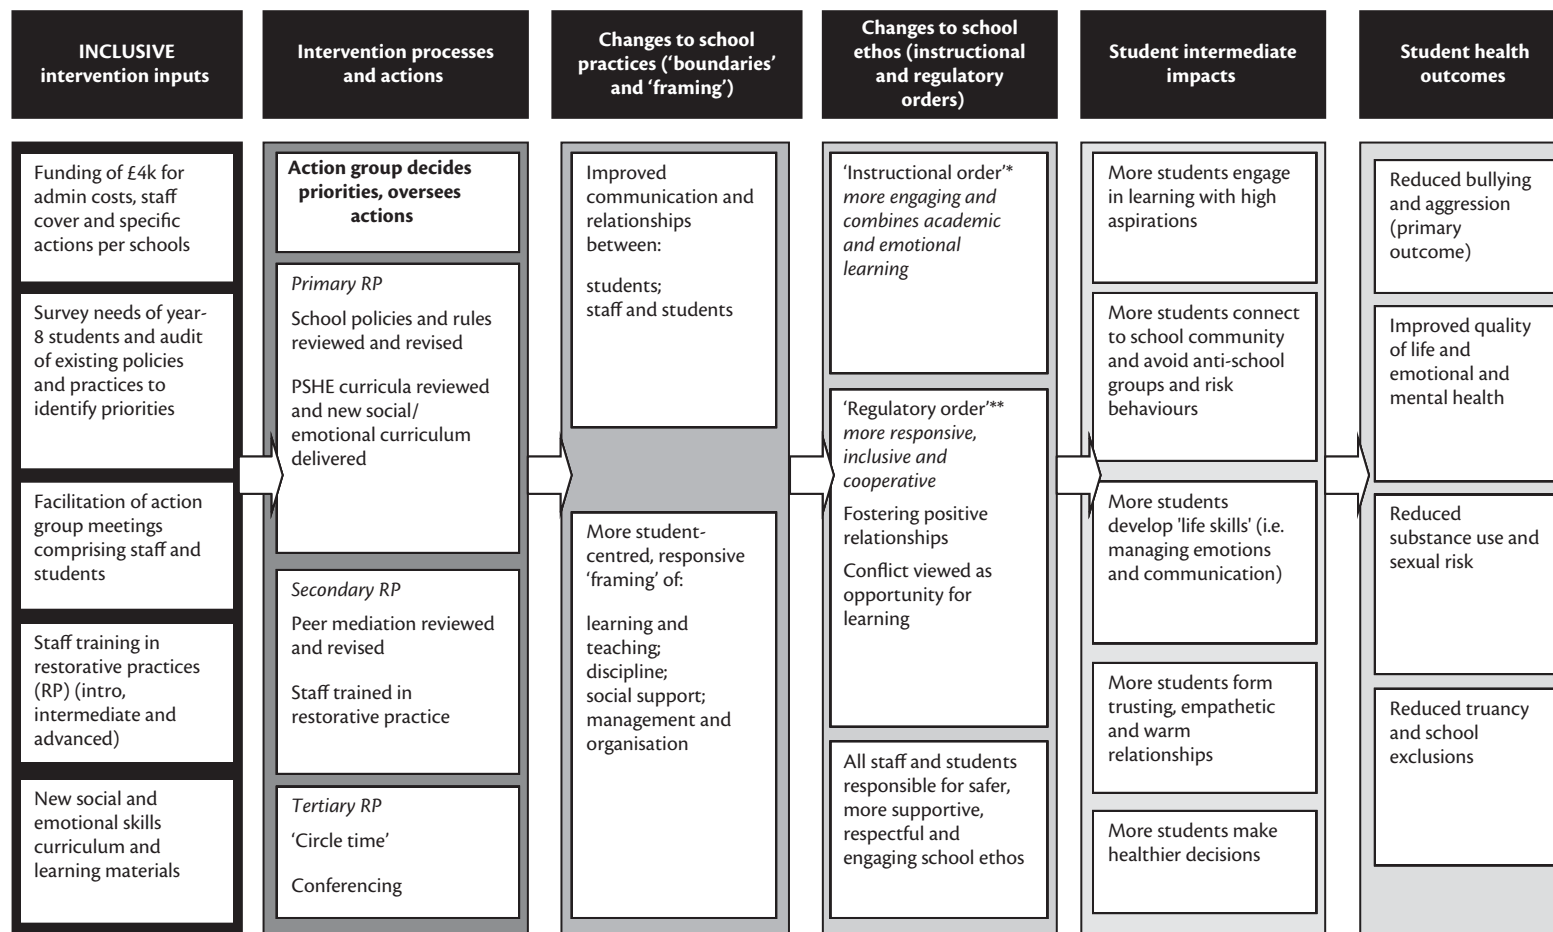

Pawson and Tilley (1997) suggest that all interventions are in essence 'theories incarnate' because they assume that a certain intervention will involve a particular causal process leading to particular outcomes. In the absence of proper theory, the assumptions made by intervention planners, providers, or evaluators remain implicit. Recent guidance on developing complex interventions advocates using explicit theories of change to inform their design (Campbell et al. 2007; Craig et al. 2008; Glanz and Bishop 2010). While interventions formulated without recourse to theory can and do work, there is increasing evidence that they are more likely to be effective when informed by theory (Noar et al. 2008; Glanz and Bishop 2010). The ASSIST peer-led smoking prevention intervention is an example of a successful

theory-based smoking prevention intervention (Campbell et al. 2008). Students aged 12–13, identified by class mates at secondary school as being influential, are trained to have conversations with their peers about the benefits of not smoking (Audrey et al. 2004). The intervention was informed by diffusion of innovations theory (Rogers 1983) with the peer supporter's role being to diffuse new attitudes and new norms of behaviour relating to smoking throughout the year group. A cluster RCT conducted in south Wales and south-west England showed a 22 per cent overall reduction in the odds of being a smoker in intervention compared with control schools. The research also included an evaluation of the process of delivering ASSIST to facilitate understanding what factors make the programme successful. This process evaluation found that ASSIST was implemented with a high degree of fidelity and was acceptable to schools and school teachers (Audrey et al. 2008; Holliday et al. 2009), and to the young people who received it. More detailed follow-on research on the peer supporters found that those who are asked to work informally, rather than under the supervision of teaching staff, engaged more effectively with the task they have been asked to undertake and more effectively diffused the health-promotions messages, in this case smoking prevention (Noar et al. 2008).

Reviews of which theories have been utilized most frequently in relation to public health interventions show that the field is dominated by psychological theories (Glanz and Bishop 2010; Davis et al. 2014). However, as we have already indicated, effective public health intervention is likely to require action at more than just the level of the individual and the National Institute for Health and Care Excellence's 2007 guidance on behaviour change concluded interventions would be more effective if they did so (National Institute for Health and Care Excellence 2007). Public health intervention research may therefore need to draw on theories from a variety of disciplines. There are useful resources available which provide compendia of theories but the range of theories included in each reflects the disciplines involved or the contexts examined (Glanz and Rimmer 1997; Conner and Sparks 2005; Nutbeam et al. 2010).

Development of intervention logic models

An understanding of intervention theory, that is, how an intervention is intended to produce its effect, is critical to planning a process evaluation. Logic models are diagrammatic representations of the logical relationships, for example, between an intervention's inputs, activities, outputs, and outcomes, although there is scope for flexibility regarding the precise categories used (Cooksy et al. 2001; Kellogg Foundation 2004). Intervention theory and logic models are useful tools in clarifying how an intervention is to be delivered and to what ends, and thereby provide a focus for evaluating process (and outcomes). Fig. 6.5.1 provides an example of a recent logic model. It is for the INCLUSIVE intervention which was designed to reduce bullying and aggression in secondary schools (Bonell et al. 2013). The intervention's theory of change is informed by Markham and Aveyard's theory of human functioning and school organization (Markham and Aveyard 2003). Its tenets inform a diagrammatic logic model consisting of inputs, processes, institutional changes, intermediate impacts, and health outcomes. Inputs include training staff in 'restorative practice' (RP) as an approach to preventing and managing student aggression and misbehaviour, as well as an external facilitator who

* i.e. learning and teaching in school ** i.e. discipline, social support and sense of community in school

Fig. 6.5.1 Logic model for the INCLUSIVE intervention to reduce bullying and aggression in secondary schools.

Reproduced with permission from Bonell, C. et al., A pilot randomized controlled trial of the INCLUSIVE intervention for initiating change locally in bullying and aggression through the school environment: final report, *BMC Public Health*, Copyright © 2013 BioMed Central.

would convene meetings of students and staff to review data on student needs in order to plan and deliver school-specific actions. These inputs are intended to enable processes, such as improved personal, social, and health education (PSHE) and the use of RP in schools, as well as the review and revision of school policies and rules by staff and students working collaboratively. In turn these processes are intended to modify various ‘boundaries’ within the school, such as the quality of staff–student relationships, and how schooling is framed, for example, to render decision-making more student-centred. These processes are ultimately theorized as transforming the ethos of the school so that more students are committed to the school’s instructional order (teaching) and the regulatory order (discipline and school sense of community) and are thus less likely to become committed to anti-school peer groups and behaviours such as bullying and substance use.

Using theory effectively in the design of interventions although highly recommended is an area where good guidance is still somewhat lacking. How to identify relevant theories from the many disciplines that relate to public health, how to use them to develop a logic model specifying the mechanisms by which change is to be achieved, and then how to translate this model into a practical public health intervention is a challenge and one for which few exemplars of good practice exist. We hope though that this is a challenge that researchers and practitioners will rise to and that there is a consequent increase in the development of effective complex public health interventions.

Evaluation of complex interventions

Piloting and feasibility studies

Before embarking on a definitive RCT or some other evaluation of the effects of an intervention, it is wise to undertake a pilot or feasibility study. These terms have tended to be used interchangeably (Arañ et al. 2010) but the National Institute for Health Research Evaluation, Trials and Studies Coordinating Centre (NETSCC) has proposed a helpful distinction (NETSCC 2014). A pilot study is in effect a miniature version of the main trial and is designed to test that both the intervention and the evaluation can be implemented as intended. If the pilot is successful and no changes are made then data from it can be incorporated into the main trial (this is termed an internal pilot as opposed to an external one where data cannot be incorporated into the main trial). In contrast, feasibility studies are intended to indicate whether or not a definitive trial is feasible and to examine important areas of uncertainty such as the willingness of participants to be randomized, response rates to questionnaires collecting outcome data, or the standard deviation of the primary outcome measure required for the sample size calculation. Such studies can have a much more flexible format and need not necessarily be randomized.

Process evaluation methods

Process evaluation is as important as outcome evaluation. Process evaluation can provide valuable insight not only within feasibility and pilot studies, but also within definitive RCTs as well as in studies examining implementation of scaled-up interventions after effectiveness trials have been completed. Process evaluations can examine how interventions are planned, delivered, and received (Bonell et al. 2006; Oakley et al. 2006).

There is no single, agreed definition of process evaluation. The UK MRC states that process evaluations ‘can be used to assess fidelity and quality of implementation, clarify causal mechanisms and identify contextual factors associated with variation in outcomes’ (Craig et al. 2008); more specific guidance is currently being drafted. Other priority areas have been identified. One of the most widely cited frameworks is that of Steckler and Linnan (2002) which identified priority areas for process evaluation, including: fidelity (the extent to which the intervention is delivered as intended), reach (whether an intervention is received by all those it targeted), dose delivered (the amount or number of units of intervention offered to participants, dose received (the extent of participants’ active engagement in the scheme), and context (local factors which impact implementation). Thus, process evaluation can explore whether those whom an intervention targets actively engage with it, an important consideration for social interventions. The following subsections consider some of these priority areas in more depth.

Intervention delivery and fidelity

The importance of process evaluation was increasingly recognized during the 1980s, spurred by publication of a paper on ‘type 3 error’, defined as concluding that an intervention is ineffective when a lack of effect actually reflects it is not being implemented as intended (Basch et al. 1985). Initially, the main aim of process evaluations was therefore to assess intervention fidelity, in order to determine whether outcomes evaluation could represent valid assessment of an intervention’s underlying theory. Fidelity is defined variously. Moncher and Prinz (1991) define fidelity as confirmation that manipulation of the independent variable occurred as planned. Within the context of a RCT or other comparative evaluation, this requires assessment of the integrity of both delivery within the intervention arm and its differentiation from what occurred in the control arm. Later definitions of fidelity, for example, by Lichstein and colleagues (Lichstein et al. 1994), saw this as also encompassing receipt (participant uptake of the intervention) and enactment (the extent to which participants apply the lessons of interventions into practice in their lives). But such definitions begin to blur the useful distinction between fidelity and factors such as dose, acceptability and even outcomes, so most researchers continue to define fidelity narrowly in terms of delivery.

Assessments of fidelity generally involve quantitative measurement, for example, using observations, video-recording, or provider self-assessments to audit actual delivery against what was intended to occur. However, fidelity should not be viewed only in terms of ticking boxes on simple checklists. Steckler and Linnan (2002) argue that when evaluating fidelity, it is also important to assess whether the ‘spirit’ of an intervention is delivered in practice, and not just its mechanics. For example, when evaluating motivational interviewing, which is counselling aimed at enabling clients to recognize their own motivations for behaviour and to modify behaviour where this is not in line with their own goals, it is important to evaluate fidelity not merely as a cook-book list of techniques, but also whether the underlying empathic, patient-centred spirit of the approach is achieved (Miller and Rollnick 2009).

Another important consideration when evaluating fidelity is the degree to which interventions should be standardized. Advocates of strict fidelity (Mihalic 2004) argue that this is essential if effective

interventions are to be replicated, especially when an intervention's 'active ingredient' may not be known. They present evidence which suggests that high fidelity is associated with greater impact for some interventions (Mihalic 2004). Advocates of local adaptation (Dane and Schneider 1998) argue that interventions need to be tailored to local circumstances. Durlak and DuPre (2008) propose a compromise whereby an intervention's 'core components' should be delivered in standard form but less central intervention components or features can be modified to fit local needs. They present research which suggests that a balance between fidelity and adaptation is likely to be most effective, with the precise balance dependent on the specific intervention. As noted earlier in this chapter, Hawe and colleagues go further to argue that with complex interventions characterized by synergistic interactions between multiple components, too much attention has been paid to standardizing the *form* of intervention components (what precise actions are delivered) and more attention should be given to standardizing the *function* of intervention components (what the aim of each component is and how it contributes to the overall aim of the intervention) (Hawe et al. 2004). Consider the case of the INCLUSIVE intervention described earlier. Fidelity of form might be measured by determining whether the training in RP was delivered as planned and whether the facilitator convened a sufficient number of staff–student meetings. In contrast, fidelity of function might be measured by determining whether teachers were equipped to deliver RP and whether staff and students felt involved in the process of reviewing school policies.

Intervention reach, dose, and acceptability

Steckler and Linnan conceive of evaluating intervention reach and dose, and participants' responses to an intervention largely in quantitative terms (Steckler and Linnan 2002). Reach and dose are commonly examined quantitatively using methods such as questionnaire surveys exploring participants' exposure to and satisfaction with an intervention. However, receipt can also be seen in qualitative terms as exploring participants' reports of an intervention in their own terms. Qualitative research can be useful in examining how participants perceive an intervention in unexpected ways which may not be fully captured by researcher-developed quantitative constructs. Qualitative research can also explore how providers or participants exert 'agency' (willed action) in engaging with the intervention rather than merely receiving it passively (Oakley et al. 2006). For example, process evaluation of a youth work intervention to reduce teenage pregnancy in England reported how some youth workers and teachers responded to onerous recruitment and retention targets by transforming the intervention from one delivered out of school hours to one delivered as a partial alternative to normal school time, which may have explained its ineffectiveness (Wiggins et al. 2006).

Context

Context is a critical aspect of process evaluation. Although there is no consistent definition, context can be taken to mean anything that was in place before the intervention itself was implemented. This could include factors such as the needs of participants, the infrastructure within which interventions will be delivered, the skills and attitudes of providers, and the attitudes and cultural norms of potential participants. In Steckler and Linnan's (2002) framework, context is largely considered in terms of factors which

may help or hinder implementation. For example, an intervention may be delivered poorly in some areas, but well in others, because of better provider capacity or more receptive community norms in some areas. Others consider context also in terms of how it influences outcomes. For example, 'realist' evaluators place great emphasis on whether interventions work more effectively in some contexts than others and how this might be explained by interactions between contextual factors and the mechanism of action of the intervention. Context can be measured quantitatively in order to inform 'moderator' analyses but this occurs rarely and inconsistently between studies (Bonell et al. 2012). Qualitative research allows for a different understanding of the importance of context, for example, examining how intervention providers or recipients describe the interaction between their context and their own agency in explaining their actions (Oakley et al. 2006).

Intervention mechanism of action

Assessing an intervention's mechanisms of effects involves assessing whether the validity of the theory of change does indeed explain its operation. Such analysis can explain why an intervention is found to be effective or ineffective within an outcome evaluation. This might be critically important in refining an intervention found to be ineffective or in understanding the potential generalizability of interventions found to be effective. Quantitative data can be used to undertake mediator analyses to assess whether intervention outputs or intermediate outcomes appear to explain intervention effects on health outcomes (Gardner et al. 2006). Qualitative data can be used to examine such pathways and this is particularly useful when the pathways in question have not been comprehensively examined using quantitative data, as well as when pathways are too complex (e.g. using multiple steps or feedback loops) to be assessed adequately using quantitative analyses. This was, for example, the case with an assessment of possible causal pathways underlying an intervention to modify school environments in order to reduce student substance use, which appeared to involve feedback loops whereby student participation within certain intervention activities increased student commitment to the intervention which in turn increased student participation within other components (Bonell et al. 2010).

However, such analyses can be challenging. First, as suggested earlier, quantitative analyses require evaluators to have correctly anticipated what data is needed to examine causal pathways and to have collected these. For example, the evaluation of the youth work intervention aiming to prevent teenage pregnancy reported a higher rate of pregnancies among those receiving the intervention. It was hypothesized that this apparent adverse outcome resulted from the intervention bringing together young people engaged in risk behaviours so that pro-risk social norms were amplified. However, data on these were not collected so that this hypothesis could not be tested (Wiggins et al. 2008). A second challenge involves using qualitative alongside quantitative data to understand causal pathways. If qualitative data are analysed in order to explain quantitative findings, this may bias interpretation (Wight 2002). Furthermore, quantitative and qualitative methods originate from different research paradigms. Qualitative research is inductive and generalizations are made from particular circumstances making the external validity of the findings somewhat uncertain. As Munro and Bloor (2010) put it: 'process evaluations do indeed enrich our understanding of the social processes

involved in the delivery and receipt of complex interventions', they provide 'interpretations to which a degree of indeterminacy is always attached that cannot be expressed in probabilistic terms. . . The continuing tension between positivist and interpretive paradigms within that research design pose problems of understanding and reporting. Not so much "paradigm peace" as "paradigm truce"'.

While we advocate process evaluation as an important evaluative tool it should not be seen as a panacea for answering all the questions an outcome evaluation cannot, nor is its use unproblematic. The range of possible domains it can focus on (delivery, fidelity, reach, dose, acceptability, context, sustainability) is wide, and resources may not be available to collect the data required to examine them all. Some may be a greater priority than others depending on the nature of the intervention and its stage of development. For example, the acceptability of an intervention is something that should predominantly be explored in a pilot or feasibility study rather than leaving it till the definitive trial, where understanding mechanism of effects may be a more pressing matter for a process evaluation to examine.

Implementation issues

Sustainability

The implementability and sustainability of new public health interventions beyond the scale required for a robust evaluation of effectiveness, to a scale capable of population impact is an important consideration. For example, it may be that a group of health promotion specialists, substance misuse experts and youth workers have been specially assembled to deliver a new intervention in secondary schools to reduce substance and alcohol misuse. This intervention is shown in a cluster RCT to be effective. The issue then becomes how can that delivery model be replicated and sustained outside of the trial so that effectiveness is maintained. The 'RE-AIM' framework (reach, effectiveness, adoption, implementation, maintenance) is useful in conceptualizing this (Glasgow et al. 1999). Its originators argue that those commissioning public health services need to know not only that an intervention is effective but that it is capable of being adopted by provider agencies and implemented by them as planned, and will reach sufficient people to achieve a population health impact that can be maintained over time (Glasgow et al. 2001).

From research into practice

The impact of research on policy and practice is increasingly recognized to occur through a gradual and indirect process of enlightenment rather than via direct effects of single studies or even reviews on single decisions (Weiss 1986; Graham et al. 2006). However, while empirically accurate this is normatively disappointing for those advocating a more direct role for evidence in informing policy (Davies et al. 2000). Now there is recognition that to be influential, research needs to engage reciprocally with policy and practice. Earlier in this chapter we highlighted the need to consult key policy and practice stakeholders and the public early in the development and evaluation of complex public health interventions. This approach is now being extended by some into a process whereby evidence is co-produced through a knowledge exchange partnership between researchers, policymakers, and practitioners using transdisciplinary action research

(Daker-White et al. 2013). This method involves academics from a variety of relevant disciplines working with policymakers and practitioners to identify what research is required, develop research questions, conduct evaluations, synthesize evidence, and implement and maintain evidence-based public health practice. The advantage of this approach is that if evaluations indicate that changes to practice are producing the desired outcomes then the capacity building necessary to sustain that whole system change is built into the approach. There are a number of examples of promising interventions (de Silva-Sanigorski et al. 2010; Chittleborough et al. 2013), including the INCLUSIVE intervention in England (Bonell et al. 2013) and the Gatehouse project in Australia, where this approach has been taken (Bond et al. 2001, 2004).

Discussion and future direction

Public health interventions can comprise policy-level initiatives implemented at a national or international level, for example the World Health Organization's Healthy Cities programme (World Health Organizations n.d.), through to brief individual behaviour change interventions to encourage reduced alcohol consumption delivered in primary care populations (Kaner et al. 2007). Interventions may be programmatic in nature with many different components such as the Northland project in secondary schools to reduce alcohol consumption, or it may be very simple, as in the example of human papilloma virus vaccination which involves three injections over a 12-month period to reduce substantially the chances of a woman having cervical cancer. Given this huge variability there is no 'one-size-fits-all' approach to their development and evaluation. What we have identified in this chapter are the key issues to be considered and the range of methods available to tackle them.

We conceive of the development and evaluation of complex public health interventions as distinct elements but ideally part of an overall symbiotic and cyclical process rather than sequential phases. Knowledge exchange partnerships between researchers and public health practitioners and policymakers are a potential way of achieving this ideal, but their effectiveness has yet to be the subject of systematic evaluation.

Economic appraisal in public healthcare: assessing efficiency and equity

David Parkin, Stephen Morris, and Nancy Devlin

What is economic appraisal?

Planning healthcare services to meet the health needs of a population always has to recognize a constraint on its aims, which is the finite availability of resources with which to meet them. There are many choices that must be made, for example, which public health and healthcare services are to be provided, in what ways, and to whom. Economic appraisal (EA) is a systematic way of analysing the consequences of such choices. It is one element of Health Technology Assessment (HTA), the uses of which include pharmaceutical and other healthcare pricing and reimbursement decisions, planning of the location of healthcare facilities, and priority setting. EA is not the only element of HTA, but it is an important one.

Similarly, the discipline of economics is not the only contributor to EA. It also requires other public health relevant disciplines such as epidemiology, statistics, and operational research. Economics contributes the rationale for EA, an overall framework for analysis, and some measurement principles and methods.

The term ‘economic appraisal’ describes a set of techniques that weigh up the costs of an action, such as providing a particular type of healthcare to a segment of a population such as a group of patients, against the benefits that it may provide. The term ‘economic evaluation’ is also used. The distinction between the two terms is that appraisal is undertaken before the action is taken, to help in deciding whether or not and how the action is to be done, and evaluation is undertaken after the action, to judge its effects. This distinction is often forgotten and these terms are used interchangeably in much of health economics. The expression ‘evaluation’ is now most commonly used in the health economics literature, but appraisal is used here because that more accurately describes the main purpose for which economic analysis in healthcare is applied in practice. The usual label given to this activity in economics is cost–benefit analysis (CBA). However, that term is often reserved in health EA for a particular technique, which is explained later in this chapter.

The principles of EA can be applied to all kinds of health interventions, from intervention at the level of the individual patient to population-based programmes, all of which may be of interest to public health practitioners. This chapter therefore does not restrict itself to activities conventionally labelled as public health,

and it also includes interventions that are not usually thought of as healthcare, such as health promotion. It does highlight the special issues that EA generally faces in evaluating public health activities, and finishes with a specific examination of those issues.

The economics of economic appraisal

EA should not be confused with financial appraisal. A financial appraisal is concerned with the monetary implications of a proposed action, such as investment in a healthcare facility or the provision to a population of one or more interventions. It examines cash expenditures and available funding to ensure that the actions taken are viable and provide a reasonable return. These cash flows are measured using accounting principles. EA shares some of the methods and principles of financial appraisal, but its aim is a more general assessment of costs and benefits and has some measurement principles derived from economic concepts. The most important of these are *opportunity cost*, *social cost*, *marginal cost*, *efficiency*, and *equity*.

In practice, these theoretical principles are hard and occasionally impossible to adhere to, but they provide a guide as to what are the best sources of cost and benefit data and to the reliability of the numbers actually used.

Opportunity cost

As with any good or service, production of healthcare requires resources such as personnel (often referred to as labour), equipment and buildings (often referred to as capital), land, and raw materials. There is a finite amount of such resources available to be converted into goods and services at any particular time, so it is not possible to produce everything that everyone in a population might want. In this sense, resources are scarce relative to the demands for them. In the economy as a whole, there are not enough scarce resources to meet all of the wants that people have, so we have to choose which wants are met and which are not met. Similarly, in the healthcare system there are not enough healthcare resources to meet all of the health needs that people have, so we have to choose which needs are met and which are not met. Of course, it might be argued that if we cannot meet all health needs,

resources should be diverted from other parts of the economy, and it is legitimate for public health practitioners to advocate that. But it would not be possible to do that indefinitely and at some point the opportunity cost would be in terms of health, not just education, welfare, and other goods and services in the public and private sectors of the economy.

Economics suggests that scarcity and the resulting necessity to choose are ubiquitous and unavoidable. This observation leads directly to an important and fundamental economics concept, which is *opportunity cost*. If scarce resources are used to produce a good or service, those resources cannot be used to produce other goods or services. Opportunity cost derives from the benefits that are forgone by not producing those other goods. Because there are many possible uses for resources, the opportunity cost of using resources in a particular way is defined as the benefits that would have resulted from their best alternative use.

When economists refer to costs, they usually mean opportunity costs. This is quite different to the more familiar concept of financial costs, the costs of goods and services and of scarce resources in terms of money. Very often, financial costs are used to measure opportunity costs, but this is not always the case. Opportunity cost and financial costs are different ways of thinking about costs, rather than separate elements of overall costs; it would make no sense to calculate them separately and add them together, for example.

Measuring opportunity costs is often difficult in practice. It is preserved in good EA practice by the separation of costing services into measuring the quantity of resources required to provide that service and calculating the value of those resources, by, for example, examining the prices of each type of resource. This is also good practice for ensuring that research can be generalized to other settings where quantities and prices may differ. For example, different countries may have very different ways of providing services, with different combinations of different kinds of personnel, facilities, and locations, as well as differing relative costs of those resources.

Social costs and benefits

A financial appraisal of a proposed action takes into account only costs that are incurred by the person or organization taking the action and benefits to the person or those who are the organizations' clients. These are referred to as *private* costs and benefits. However, in some kinds of EA it is in principle essential to take account of all costs and benefits to society, whatever they are and whoever incurs them. In particular, it is essential to take account of *social* costs and benefits in a CBA that examines the impact on the economy as a whole. For example, the total costs of a medical intervention would include not only costs incurred within the health sector, but also those incurred in subsequent personal care and support, whether by organizations or private carers. However, it is arguable that such wider costs should not be included in a cost-effectiveness analysis (CEA), in which the aim is to maximize healthcare outcomes within a limited budget.

A special example of the difficulties involved in this is *transfer payments*, for example, social security payments and other state benefits paid out of taxation. Except for the costs involved in administering them, these are not costs to society as a whole. Rather, they are transfers between different members of society, since the recipients derive benefits from them that match the costs

to taxpayers. However, from the state's point of view such expenditure may be regarded as a use of tax revenues which has an opportunity cost in terms of other government expenditure.

Again, this principle is almost impossible to follow perfectly because of information limitations. However, it is preserved in good practice in health EA by examining costs and benefits according to who bears them, in three categories: the health service, patients and their families, and the rest of society. It is also embodied in the recommendation that any analysis should make clear the perspective from which the analysis is conducted, for example, society, the government, or the health sector.

Marginal costs and benefits

The total cost of any activity is likely to depend on how much of it is carried out, for example, the total cost of a vaccination scheme will depend on the number of people to be vaccinated. In estimating these total costs, an obvious solution is to multiply *average* costs per unit of activity, which are the accounting data most usually made available, by the number of units. However, in some circumstances that may mislead, and what are required are *marginal* costs. Again, the same is true for benefits.

The definition of a marginal change is that it is a change in an economic variable, such as the measure of benefit or cost that is caused by the smallest possible change in another variable. For example, the marginal cost of a good is most widely defined as the extra cost incurred in producing one more unit of it. Note that marginal does not mean small or unimportant; instead it means at the margins of an existing state of affairs, for example, the cost or benefit that will be incurred or gained by changing the allocation of resources slightly. That cost could actually be rather large, even though the change in the amount of the good is small. As an extreme example, suppose that the good is a particular screening programme and the screening centre processing the test material has reached full capacity. Screening an extra person could only be carried out if a new screening centre was built, so its marginal cost would be very high. By contrast, the marginal cost of the last test performed within the existing capacity may have been quite small, simply the cost of performing the test. This demonstrates another important point. Marginal cost may vary considerably with respect to the same size of change in the other variable, depending on the level of that other variable, in this case the number of people screened.

An example of the importance of looking at marginal costs is the impact of schemes designed to lower hospital inpatient surgical costs by reducing length of stay through earlier discharge. Hospitals may have information on the average cost of an inpatient stay, which can be used to calculate an average cost per day. However, the costs of an inpatient day are not constant. In particular, they may be much smaller than the average towards the end of the stay, because the average includes a share of the costs of treatment and perhaps of high dependency care that took place towards the beginning of an inpatient stay. So, reducing the number of low dependency days at the end of the stay will save far fewer resources than would be expected by examining the average. Marginal costs calculated with respect to an increase or decrease in the number of days would give a correct estimate of the likely savings.

Similarly, it will be important to examine marginal benefit, for example, as the extra benefit gained by the consumption of one

more unit of a good. An example of the importance of looking at marginal rather than average benefits is a screening programme that can be carried out with different numbers of sequential tests. The more tests, the more cases are detected. A programme that used two tests might yield 11 cases per 1000 people tested, which could look reasonable. But suppose that a one-test programme would discover ten cases. If instead of analysing these as a one-test screen and a two-test screen, the two-test programme is analysed as one test followed by another, the marginal benefit is only one case, which does not look so good.

To give a real example, Torgerson and Spencer (1996) illustrated the importance of marginal analysis by analysing data on the cost-effectiveness of biochemical screening for Down's syndrome as a replacement for screening by maternal age. An estimate had been published that introducing biochemical screening in a population of 20,000 pregnant women would cost £413,501 and might prevent 11 affected births, giving a cost-effectiveness ratio of £37,591 per affected fetus identified. Torgerson and Spencer pointed out that for the same number of women, existing antenatal screening procedures based on maternal age and additional tests already cost £79,500 with four births potentially prevented. So, the true cost-effectiveness of biochemical screening was $(£413\,500 - £79\,000)/(11 - 4) = £334,500/7 = £47,786$, a much higher cost per affected fetus identified than for the estimate based on average cost.

Efficiency and equity

Economic analysis is usually employed to judge the way in which scarce resources are employed according to two main criteria: efficiency and equity. These two concepts have technical definitions, which will be described in the following subsections, but in very broad terms efficiency refers to obtaining the greatest output for a given set of resources and equity refers to a fair distribution of that output amongst the population. The term 'output' is very general and in our context we usually mean the additional amount of healthcare or health produced.

Efficiency

It is necessary to give a warning about definitions of efficiency. Economists, as specialists in the analysis of efficiency, largely agree about what it means and how different types of efficiency may be defined, but the labels they give to those types vary. The same concept may be given different names and the same name given to different concepts. Here we use the labels and definitions given in Morris et al. (2012).

Knapp (1984) gave a very broad definition of efficiency as 'the allocation of scarce resources that maximizes the achievement of aims'. This is a useful start, because it suggests the very benign nature of the desire to achieve efficiency. If we have scarce resources and competing uses for them, our aim will be to obtain the best set of uses, with 'best' defined in whatever way we want. If we decide that the aim of the health system is to improve the health of the population and we have a fixed healthcare budget, we will obtain the biggest health gain if the allocation of scarce healthcare resources is efficient.

For practical purposes, we require more precise and technical definitions of efficiency. However, it is useful first to understand a slightly abstract idea, called Pareto efficiency (named after the nineteenth-century economist Vilfredo Pareto who introduced

the concept), which is also (though not consistently) called *allocative efficiency*. This arises from an attempt to create a widely acceptable criterion for judging different allocations of resources to different ends. The suggestion is that we would be able to say that one allocation is better than another if at least one person is better off under the first allocation and no one is worse off. This is called the Pareto *criterion*. If we change from one allocation of resources to another, for example, if it were possible to make changes to the healthcare system in terms of the kind of care that is made available, and this means that some people benefit and no one is made worse off, then this is described as a Pareto *improvement*. If it is not possible to make any such changes, then we have achieved a Pareto *optimum*. Another way to view the Pareto optimum is that it is a position where it is not possible to make anyone better off without making someone else worse off.

If our aim is to make people as well off as possible and we are not concerned about whether some people are better off than others, then a Pareto optimum is efficient. We cannot further improve the achievement of our aim because even if we can make someone, or even many people, better off, we do not know if this is outweighed by those who are made worse off. Of course, there are many allocations of resources that would be Pareto optimal, some of which would imply great inequalities between different people. If our aims also took account of the undesirability of inequalities, then we might not view all Pareto optimums as efficient. Nevertheless, ideas of efficiency in economics do derive from this concept of Pareto efficiency. Here, we define three types: *technical*, *economic*, and *social*.

Technical efficiency is a concept that is used in considering how health and healthcare, which we may call 'output', are produced from scarce resources, or 'inputs'. Technically efficient production is achieved if we are producing most output from a set of inputs, or producing a set amount of output using the fewest inputs. For example, the number of people that can be vaccinated against influenza in a general practice clinic depends on the number of nursing staff that are available and other inputs. If the most that can be provided by three practice nurses is 100 vaccinations each day, then it is technically inefficient to provide 99 vaccinations with that number of nurses or to provide 100 vaccinations with more nurses.

Another way of viewing technical efficiency, which is consistent with Pareto efficiency, is that the practice cannot vaccinate more people without employing at least one more nurse. More generally, production is technically efficient for a given set of inputs if it is only possible to produce more by employing more of at least one input.

In practice, EA does not directly address technical efficiency, though as will be explained it is an essential underlying assumption in most cases.

Economic efficiency has a number of different labels, including cost-effectiveness, though that term should be used carefully, as will be explained below. Technical efficiency is defined with respect to the physical numbers of inputs, but economic efficiency is interested in the cost of those inputs. Economic efficiency is achieved if we are producing most output for a given cost, or producing a set amount of output at the lowest possible cost. Using the earlier example, suppose that people could be vaccinated by different grades of nurses, but at least one senior nurse must be part of the team. It might be equally technically efficient for 100

people to be vaccinated each day by employing one senior and two junior nurses, one junior and two senior nurses, or three senior nurses. But senior nurses are more expensive to employ than junior nurses, so it will be economically efficient to use the first of these staff mixes. This demonstrates that although achieving technical efficiency is necessary to achieve economic efficiency, not all technically efficient ways of producing are economically efficient.

Another way of viewing economic efficiency, which is consistent with Pareto efficiency, is that given the costs of employing nursing staff, the practice cannot undertake more treatments without them costing more to provide. More generally, production is economically efficient for a given set of input prices if it is only possible to produce more by incurring greater costs.

In practice, economic efficiency is the dominant type of efficiency analysed in EA. However, there are different ways in which this is done, as will be explained below.

Social efficiency is a much broader concept than technical and economic efficiency. If there is economic efficiency in production in every part of the economy, there is *allocative efficiency in production* for the economy as a whole. There is an equivalent concept relating to the consumption of goods and services called *allocative efficiency in consumption* where, given prices of goods and services, consumers maximize the benefit that they derive from those goods and services. If *both* of these are achieved, then there is allocative efficiency in the economy as a whole, which is also known as social efficiency. This is the same as the Pareto efficiency described earlier.

Obviously, social efficiency according to this strict definition is not a concept likely to be of practical use in health economics. However, it is important because it underlies CBA, whose aim in theory is to move the economy closer to social efficiency.

Equity

Equity is an important criterion for allocation of resources, and it is particularly important in health systems because it is observable that people attach more importance to fairness in health and healthcare than to the distribution of many other goods and services. Almost every healthcare system in the world has equity as an important policy objective. However, economic analysis of equity is less clear than that of efficiency, except for how equity might be measured, and there is less agreement amongst economists about it.

Equity means fairness, and in the context of healthcare this means fairness in the distribution of health and healthcare between people and in the burden of financing healthcare. It is not a synonym for equality, which means an equal distribution. It may not always be fair to be equal, for example, it might be thought to be unfair if both healthy and sick people are given the same amount of healthcare. But equality is often used to define equity, as, for example, in the principles of *horizontal equity*—the equal treatment of equals—and *vertical equity*—the unequal treatment of unequals. An example often used in healthcare is the proposal that there should be equal access to healthcare for people with the same level of healthcare needs.

However, that is not the only possible definition of healthcare equity, and more generally there is no single definition of what equity is. Moreover, ideas about equity are not mainly founded on economics principles, rather on philosophy, ethics, law, and other forms of enquiry. An example is the equity principle of procedural justice, which in this context might mean that the process used

to decide on the allocation of healthcare resources between people should be fair. This is an important principle in deciding how HTA is applied, but it is not especially based in economics. Culyer and Bombard (2012) have suggested that one way to incorporate the plurality of approaches to equity in HTA is to use a 'checklist' to ensure that decision-makers take all aspects into account.

It is necessary to consider what it is that we wish to be equitable about. Three areas in which equity may be considered are the finance of healthcare, the distribution of healthcare, and the distribution of health.

Analysis of equity in the finance of healthcare mainly concentrates on vertical equity, with a particular emphasis on whether or not healthcare is financed according to people's ability to pay. Horizontal equity in financing considers whether or not people, who have the same income, and therefore the same ability to pay for healthcare, make the same payments.

Horizontal equity in the distribution of healthcare mainly examines whether or not people with the same need for healthcare make the same use of healthcare services. Vertical equity in the distribution of healthcare is usually interpreted to mean whether individuals with different levels of ill health have different levels of use that are appropriate to that difference.

Equity in the distribution of health is almost always expressed in terms of inequalities in health. Health inequalities, particularly those that demonstrate that health levels vary systematically and inversely with socioeconomic status, are always of some importance in health policy debates and a major concern of some governments, depending on their political preferences. It may be argued that this is in fact the only real equity concern, since a concern for equity in healthcare derives solely from a concern about the distribution of health.

Formulating an economic appraisal

One way to look at how an appraisal is carried out is to consider it as a process with stages, as follows:

1. Defining the problem to be analysed. The problem is always the starting point of an appraisal. This may seem obvious, but in fact it is often solutions that are, wrongly, regarded as the starting point. From an appraisal point of view, the problem is not whether a fluoridation programme is cost-effective, but what is the most cost-effective way to deal with the problem of dental caries.
2. Specifying the alternatives, which include different ways of dealing with the problem defined in the first stage. It is important to select the most relevant alternative whatever it is, for example, promotion of tooth-friendly nutrition amongst children, or doing nothing.
3. Assessing costs and benefits which has three elements:
 - ◆ *Enumeration* of costs and benefits, which means the drawing up of a descriptive list of the costs and benefits that are to be included in the appraisal.
 - ◆ *Measurement*, which means obtaining data to describe the levels of costs and benefits for the different alternatives.
 - ◆ *Valuation*, which is required to convert the data into values. For example, data on resource use should be converted into costs by applying to those data the value of the resources.

4. Calculating results means combining the data on costs and benefits into the results that will be presented. The exact nature of this will depend on the type of appraisal that is carried out and how uncertainty over the results is dealt with.
5. Making a decision. The endpoint is when a decision is taken on the basis of the appraisal. This will not be taken by an appraiser, but by someone who has the responsibility to make a decision. However, appraisers often do recommend a decision which is based on their own appraisal, or imply such a recommendation. This is legitimate if the relevant decision rules are known. For example, there might be an accepted decision rule that states that if the benefits of a health intervention exceed its cost then it should be provided to the population. A finding, for a particular intervention, that its benefits did exceed its costs may then lead to a recommendation that it should be provided.

One important factor in this is that an appraisal should be formulated and carried out with full awareness of which viewpoint is being taken. This arises because different actors in the health system—patients, health professionals, and government, for example—may have different interests and concerns, so that what is efficient from one point of view may not be from another. This is important because it determines which type of appraisal is to be used, what constitutes a benefit and a cost and how these are to be valued. Most appraisals will take the viewpoint of the health service, since that embodies most of those who have the legitimacy to decide which healthcare is to be provided. However, they may also take the viewpoint of society as a whole, since that defines the recipients of healthcare as well as the ultimate funders of it. Whatever viewpoint is adopted, researchers should be explicit about which it is. In EAs of public health interventions, a broader perspective is frequently taken, to account for costs and benefits that occur outside the health system.

Types of economic appraisal

Although there are several different types of EA, we will concentrate here on those most likely to be encountered in healthcare and other public health activities. Unfortunately, there are different ways in which these types can be classified. This leads to occasional disputes about how results of a particular type of appraisal should be interpreted or used. One way is to classify them according to what kind of efficiency they analyse. A second way is to classify them according to which costs and benefits are measured and how this is done. A third way is to classify them according to the type of decision that they apply to. Although we will discuss all three types here, the most widespread and popular classification in health economics is given by Drummond et al. (2005), which uses both the measurement and decision type principles.

In what follows, we refer to what is being appraised as alternatives, reflecting the use of EA in healthcare in decision-making about alternative ways of using healthcare resources. This includes many kinds of decisions, including different ways of delivering healthcare, different types of healthcare and different treatment options.

Cost–benefit analysis

In economics more generally, CBA starts with an inventory of all of the costs and benefits of each of the alternatives, whatever

they are and whoever incurs them. This can be regarded as a balance sheet in which costs and benefits are weighed up against each other.

However, in healthcare appraisals CBA is usually defined, following Drummond et al. (2005), as a technique in which all costs and benefits are measured in terms of money. The rationale for this is that it is only possible to weigh up all of the costs and benefits if they are measured in the same unit. Although in principle any common unit could be used, in practice money is the obvious and natural choice, as it is the measure of value most used in modern economies. The result of such a CBA would be to establish which of the alternatives has the greatest net benefit, the difference between benefits and costs, which could of course be negative.

The main decision rule for CBA is that an activity should be undertaken if the sum of the benefits is greater than the sum of the costs or, identically, if the net benefit is positive. If only one activity with a positive net benefit can be undertaken (because, for example, there are limited funds), then the rule is to choose the activity with the highest net benefit.

CBA is based on economics theory, because if all of the costs and benefits are measured in the correct way—for example, all costs measure their true opportunity costs—and an alternative has a net benefit, it will lead to a Pareto improvement. The way that this has been interpreted by Drummond et al. (2005) is that CBA is therefore appropriate for answering questions about whether or not a healthcare programme should be implemented or a treatment should be used, rather than which of a number of alternative programmes or interventions is the most efficient.

Because CBA requires benefits to be measured in financial or monetary terms and to cover a very wide range of costs and benefits, it is rarely used. An example in public health is Wang et al. (2005), who estimated a limited range of costs and benefits of using bike and pedestrian trails to reduce healthcare costs arising from inactivity. They calculated that the annual cost per person of using the trails was US\$209.28 and the resulting reduction in medical costs was \$564.41. This gives a net benefit of \$355.13 per person.

Investment appraisal

Investment appraisal in the context of healthcare can be explained using the example of a specific technique called by the United Kingdom's finance ministry (the Treasury) *option appraisal*. This is described in the guidance that it gives to public bodies about how they should appraise and evaluate projects that are to be paid for from public funds; the distinction between appraisal and evaluation is carefully kept to in this case. It is a process in which different options for meeting an objective, defined by the aim of meeting some public need, are generated; CBA is applied to these options; and the best solution for meeting the aims is chosen on the basis of the results. For example, an appraisal of a project for setting up a new national programme for measuring obesity among schoolchildren would not start as a comparison of the new programme with the existing circumstances. It would start with the need to understand the extent of obesity among schoolchildren, generate different options for dealing with that need, which might include a new measurement programme, examine the costs and benefits of each alternative, and from this derive the economic case for the new programme, if it was found to be the best alternative. The economic case for the project would simply be part

of a more general project appraisal including affordability and achievability and various types of impact assessment including on health, the environmental and health and safety.

Cost–consequences analysis

Cost–consequences analysis (CCA) is a form of CBA which does not try to put all of the costs and benefits into the same units. In particular, it accepts that there are different types of benefits that cannot be measured in the same units. This distinguishes it from CEA, which is discussed in the following subsection. The assumption is that in making decisions based on a CCA, different decision-makers will place their own weights on the different benefits and on costs, implicitly if not explicitly. CCA is of particular interest in public health because it is argued that it is more suitable for population health issues involving a wide range of agencies and of differing and incommensurable outcome indicators. For example, the National Institute for Health and Care Excellence (NICE) in England permits CCA to be used for public health interventions, unlike other healthcare. CCA is often referred to as a disaggregated approach, because the benefits and costs are not combined into a single indicator such as net benefit or a cost-effectiveness ratio, which are defined below.

Cost-effectiveness analysis

Cost-effectiveness derives from the analysis of economic efficiency, where one alternative is preferred to another if it provides greater benefit at the same or lower cost, or lower cost for the same or greater benefit. This definition leaves open the question of which of two alternatives is more efficient if one provides greater benefit than the other, but at a lower cost. However, under certain conditions, for example, that the alternatives can be reduced or increased in size to produce any level of total cost or benefit, such comparisons can be made. A cost-effectiveness ratio (CER), defined as costs divided by benefits, can be calculated in order to do this. The CER most often used in health economics is called an incremental CER, or ICER, where the costs and benefits of each alternative are calculated compared with their next best alternative, rather than with a common alternative.

The measurement principle for CEA is that costs are measured in terms of money, but that benefits are measured in units other than money. However, unlike CCA, all of the benefits are measured in the same units, usually because only one type of benefit is considered. The obvious consequence of this is that costs and benefits are not weighed against each other. The ICER simply shows the cost of obtaining a unit of benefit. Whether that cost is worth incurring is a different question. So, unlike CBA, which tells us whether or not health programmes or treatment are an efficient use of resources, CEA tells us which of the possible ways of providing those is the most efficient.

Drummond et al. (2005) restrict the use of the term CEA in two ways. First, they regard CEA as being applicable only when both the costs and benefits differ between alternatives. The case where benefits are the same but costs differ is called *cost-minimization analysis* (CMA). In practice, this term is rarely used to describe analyses that have been carried out, although such analyses may well be quite widespread. Secondly, they restrict the measurement of benefits to be in what they call *natural units*, such as numbers of cases detected, changes in clinical measures like blood pressure or changes in undesirable biological markers. This contrasts with

the measurement of benefits in terms of changes in health-related quality of life, which is often given the label *cost–utility analysis* (CUA), discussed in the following subsection.

The first decision rule for this kind of CEA is that we should reject any alternatives that are *dominated* by another alternative or combination of alternatives. This is economic efficiency in the strict sense described earlier, where the dominated alternative has a greater cost with no greater benefits or lower benefits with the same or greater costs. The choice between non-dominated alternatives is more complex. Where only one alternative can be chosen, that with the lowest ICER should be chosen, but only if it is below a *ceiling ratio*, which is a level of the ICER which any alternative must meet if it is to be regarded as cost-effective. Where combinations of more than one alternative can be used, it is in principle necessary to calculate the ICERs for every possible combination to decide which is most efficient and if any meet the ceiling ratio requirement.

These issues are often illustrated using a *cost-effectiveness plane* diagram (Black 1990), as in Fig. 6.6.1. ICERs are presented graphically as a combination of the costs and the effects of a health intervention, described in Fig. 6.6.1 as a treatment, compared to some alternative. Costs are conventionally placed on the north–south axis and effects on the east–west axis. In both cases, these effects can be negative, zero or positive.

The ceiling ratio can be also be demonstrated using a cost-effectiveness plane diagram, where it is often referred to as demonstrating *cost-effectiveness acceptability*, as in Fig. 6.6.2.

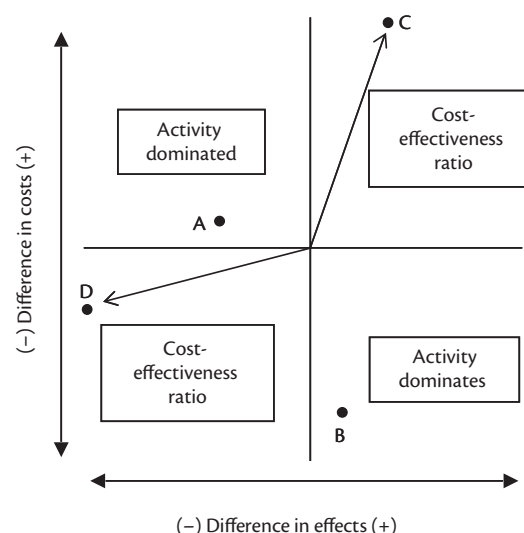

Fig. 6.6.1 The cost-effectiveness plane. An intervention can be placed anywhere on this diagram according to its incremental costs and benefits. If it lies in the north-west quadrant, such as point A, the costs of the intervention are higher than the alternative, and its benefits are lower. It is therefore unambiguously worse, and is said to be dominated by the alternative. Similarly, in the south-east quadrant, at a point such as B, costs are lower and benefits are higher, so the treatment dominates its alternative. In the north-east quadrant, at a point such as C, higher benefits are gained at a net cost over the alternative. So, we can calculate an ICER, the cost per unit of effect gained, measured as the slope of the line from the origin to the point. In the south-west quadrant, at a point such as D, lower costs are possible, but at the expense of lower benefits. Again, we can calculate an ICER, although this now refers to a cost saving per unit of effect lost, which is again measured as the slope of the line from the origin to the point.

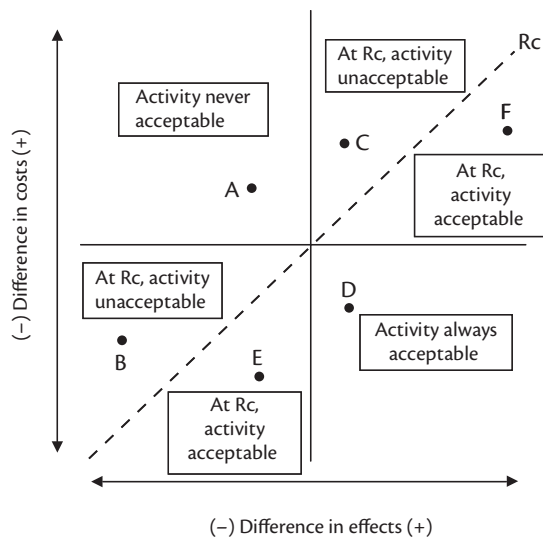

Fig. 6.6.2 Cost-effectiveness acceptability. In this diagram, the dotted diagonal line marked R_c represents the ceiling ratio. If an intervention lies above the line, it will not be acceptable on cost-effectiveness grounds. This is either because it is dominated by the alternative, whatever the ceiling ratio is, as in point A, or its ICER does not satisfy the actual ceiling ratio, as in points B and C. It should be noted that in the south-west quadrant, this means that the ICER is below the ceiling ratio, as in point B, while in the north-east quadrant it is above, as in point C. Below the line it will be acceptable. This is either because it dominates the alternative, as in point D, or its ICER satisfies the ceiling ratio, as in points E and F. In this case, the ICER is above the ceiling ratio in the south-west quadrant, as in point E, or below it in the north-east quadrant, as in point F.

Cost-effectiveness acceptability is also important because it is one way in which uncertainty in EA is dealt with, which is explained later in this chapter.

Cost-utility analysis

CUA is a term often used in the United Kingdom and elsewhere, though rarely in the United States, to refer to a special form of CEA in which health benefits are measured in terms of quality-adjusted life years (QALYs). QALYs are a composite measure of gains in life expectancy and health-related quality of life, described in more detail in the 'Measuring benefit in terms of health gain' subsection, along with disability-adjusted life years (DALYs). The distinctive outcome of a CUA is the calculation of an ICER in terms of the extra cost per QALY gained (CQG), which may also be thought of as the price of obtaining one extra QALY using a particular healthcare intervention or programme. An example is described in Box 6.6.1.

The rationale for CUA is more complex than that of CEA more generally. QALYs in themselves are regarded by many as a better outcome indicator than the 'natural' units of CEA when appraising therapeutic alternatives for the same condition. This is because they deal with efficiency in the production of health itself rather than simply of healthcare. But CUA also offers something that CEA more generally cannot, which is the possibility of comparing across treatments for different conditions. In principle, it is possible to compare interventions for, say, eating more healthily to reduce weight with, say, reducing alcohol consumption, to determine which is the most efficient at producing health gain in the form of QALYs. Of course, this is controversial. For a CEA

Box 6.6.1 A cost-utility analysis of vaccinating schoolgirls against HPV infection

Anonychuk et al. (2009) investigated the cost-effectiveness of vaccinating 12-year-old girls against human papillomavirus (HPV) types 16 and 18 to prevent cervical cancer. The vaccine also cross-protects against other HPV types, and its overall effectiveness is determined by herd immunity effects, the consequent reduction in the risk of infection to non-vaccinated people. For each 100,000 girls vaccinated, between 390 and 633 cases of cervical cancer and 168 and 175 deaths would be prevented, depending on whether or not herd immunity and cross-protection effects are included. This would generate QALY gains of 0.0083 to 0.0095 per person over the group's lifetime. There would be an increase in cost of Can\$256 to Can\$263 per person. For the base case of no herd immunity or cross-protection effects, Table 6.6.1 shows the costs and effects with and without vaccination.

This gives an extra cost per QALY gained (CQG) of Can\$263/0.0083 = Can\$31 687. With cross-protection, the CQG was Can\$26,947; with herd immunity Can\$27,849; and with both Can\$18,672. The authors concluded that the vaccine reduced cancer cases and mortality and was cost-effective, though that conclusion does depend on an assumption about the size of the ceiling ratio.

Table 6.6.1 Incremental costs and QALY gains from vaccination

	Non-vaccinated	Vaccinated	Difference
Total cost (Can\$)	476	739	263
Total QALYs	30.5015	30.5098	0.0083

restricted to different treatments for a particular condition, it can be assumed that the patients receiving the treatments are the same people, but this will not be true of comparisons across conditions.

CUA has, in principle, the ability to compare across all health interventions. A contentious implication of this is that it can be used to allocate healthcare resources between different health programmes, and therefore be used to determine healthcare priorities. That would overcome the principal problem that CEA has compared with CBA, because it would indicate whether or not the healthcare benefits from a particular type of healthcare should be realized, rather than simply which is the best way of achieving those benefits. Some people therefore regard CUA as a limited form of CBA rather than a special form of CEA. Viewed in this way, CUA is better than CBA, because it avoids having to measure benefits in terms of money.

To explain this further, recall that a decision rule for CEA is that the ICER of the best alternative is compared to a ceiling ratio. In the case of CUA the ICER is the CQG, so the ceiling ratio is the amount that we think it is reasonable to pay to gain a QALY. This is sometimes referred to as a CQG *threshold*, because it is the

dividing line between healthcare that is regarded as cost-effective and that which is not. NICE has a threshold, which it regards as deriving from the limited budget that the National Health Service has, which determines what can be afforded. This is known as the shadow price of a QALY. Alternatively, it could be set according to what the population is willing to pay for health gain. This is known as the social value of a QALY. But either way, if this is known, it can in principle be used as a means of converting costs to QALYs or vice versa. This puts costs and benefits into the same units, enabling the calculation of net benefits in the same way as for CBA.

Net benefits can be calculated in terms of either money or QALYs. Suppose that an intervention has incremental costs of £30,000 and incremental benefits of 2 QALYs. The ceiling ratio can be regarded as the price that it is acceptable to pay for a QALY, and therefore represents the money value of a QALY. Suppose that the ceiling ratio is £20,000 per QALY gained. If we decide to analyse cost-effectiveness in monetary terms, we first multiply the QALY gain by the ceiling ratio to give the money value of the QALY gain, in this case $2 \times £20,000 = £40,000$. The net cost is then subtracted from this to give a net monetary benefit of $£40,000 - £30,000 = £10,000$. Alternatively, we could convert the costs to their QALY gain equivalent by dividing the ceiling ratio by them. This would give a net cost equivalent of $£30,000/£20,000 = 1.5$ QALYs, and an overall net health benefit of $2 - 1.5 = 0.5$ QALYs. Because these are positive—and they must always have the same sign—the intervention is deemed cost-effective.

Of course, this is exactly the same result as if we had calculated the ICER to be $£30,000/2 = £15,000$ and observed that it is below the ceiling ratio of £20,000. However, this net-benefit approach does have an advantage if we do not know the ceiling ratio, since we can calculate net benefits for any value of the ceiling ratio.

Measuring costs

As suggested earlier in the chapter (see ‘Formulating an economic appraisal’), the process of costing involves three steps: identifying and describing resource use changes; quantifying them in physical units; and valuing them.

In general, there are two types of costing: macro or top-down costing and micro- or bottom-up costing. These are distinguished by the level of disaggregation at which individual resources are measured and valued. In its pure form, macro-costing starts with the total costs incurred by, for example, a hospital and calculates the costs of, for example a specialty, by allocating a proportion of the total costs to it using some indicator of the costliness of that specialty compared with others. For example, if a specialty had 20 per cent of the hospital’s cases, 20 per cent of the costs would be allocated to it. At the extreme, micro-costing would examine every item of service and every consumable used by every patient. Each item of service would be costed by examining all of the time spent on it by every member of staff as well as the time spent using every piece of equipment. In practice, these extremes are not found. Moreover, it is common for mixed methods to be used for different elements of cost.

The time at which resources are utilized is an important consideration, as not all costs are incurred at the same time. There are two important elements to this. First, if costs occur in different years, then they should be adjusted for any inflation or deflation

that has occurred. This is to make the figures comparable over different years and to ensure that it is the value of resources that is considered, which may be unaffected by the rate of inflation. The best practice is to select 1 year’s unit costs and apply them to different years’ resource use. But that is rarely possible for many items of cost, so the procedure is to deflate yearly costs by a cost index. This also means that if there are any cost projections, these should not take account of projected inflation.

Secondly, although inflation-adjusting means that each year’s costs are measured in the same units of value for each year, this does not mean that every year’s costs are of the same value when viewed from a particular year. In particular, people in general prefer to postpone costs if they can, and therefore a cost now has a higher weight than exactly the same money cost incurred in the future. Looked at another way, costs in the future have a lower value now. This is dealt with by *discounting*, which is a time weight applied to costs, which diminishes the further in the future the cost is. In practice, what is done is to apply a discount rate, which can be viewed as the inverse of an interest rate. Applying an interest rate to an investment means that the value grows over time even if it is fixed. Applying a discount rate means that the value falls over time. In an EA, if costs are summed over time, then discounting all future costs back to the present gives a present value.

The issue of timing may be very important in healthcare, because of the long-lasting effects of many interventions. (Benefits in the future may also have a lower value now, requiring the same approach; this is discussed later in the chapter, see ‘Measuring benefit in terms of health gain’). Of particular public health interest is the problem that prevention incurs costs now, and even if it reduces costs in the future by a greater amount, there may not be a net cost saving if the future costs are discounted. Even if there is a net cost saving, it will have a lower value than if discounting was not used. In the extreme, measures to deal with maternal nutrition to reduce illness in the later adult life of their babies, as suggested by the Barker hypothesis (Barker 1992), might see cost reductions so many years in the future that discounting would reduce them to a negligible value.

There is some dispute about exactly what the discount rate to be used should be, and how it should be obtained. There are two competing theories to guide this. One is the social opportunity cost approach, which assumes that public and private investments compete for resources, so the public sector should use market rates of borrowing. The other is the social rate of time preference, which measures what people are willing to receive in compensation for delaying consumption from one year to the next.

Measuring benefits

Measurement of benefits in terms of ‘natural’ units in a CEA does not require any special economic analysis, and the measurement of diverse benefits within a CCA is too diverse to be dealt with here. This section therefore concentrates on the measurement of *health gain* for use in a CUA, and the measurement of *monetary gain* for use in a CBA.

However, a third technique, which does not fit neatly into these two categories, is becoming increasingly important, the *discrete choice experiment* (DCE). In this, respondents are offered a choice between different interventions, which are described according to attributes that may include health outcomes and price. The choices

made reveal the relative values of different attributes. This might be used to ascribe a value to different interventions, or to calculate values in terms of money or to obtain values for different health states. The last of these is described in the following subsection.

Measuring benefit in terms of health gain

There are many different ways in which health and improvements in health can be measured. Different concepts and measurement techniques are appropriate for different uses. The approaches that are adopted for use in EA are largely determined by the requirements that their use for appraisal purposes dictates.

First, appraisal is attempting to obtain an unambiguous measure of benefit. This implies that the measure of health should be a single number representing all relevant aspects. Secondly, because appraisal looks at the use of scarce resources that could be devoted to all sorts of healthcare, the measure of health should be capable of comparing those different uses of resources. This implies that a generic measure of health should be used. Thirdly, appraisal compares costs, which represent the value of resources used with benefits, which implies that the measure of health should also be capable of being interpreted as a value.

One measure that meets these requirements is the QALY. This combines length of life and quality of life into a single indicator. Depending on the type of health gain, QALYs can be thought of as a quality adjustment to years of life gained or the length of time for which quality of life is improved or both. It is important to remember that the benefit of a health intervention is the gain in QALYs that it produces. A similar measure is the DALY. This chapter does not describe DALYs fully; such details can be found in Chapter 5.17, which compares the two measures. Essentially, however, the DALY is a population-based measure that combines life expectancy in a population with the prevalence of disability to generate an estimate of a 'health gap'.

Fig. 6.6.3 illustrates how in principle QALYs are calculated, for a highly stylized description of prognoses for a disease with and without treatment. For example, suppose that with a particular disease, the prognosis is that a person will live for a further 10 years. During the first two of those, their health-related quality of life (HRQOL) will deteriorate at a constant rate from 80 per cent of full health to 60 per cent and during the last eight will deteriorate more slowly to 30 per cent by the time of their death. This is represented in the diagram by the solid line, with HRQOL

values of 0.8 at time t , 0.6 at $(t + 2)$ and 0.3 at $(t + 10)$. With treatment, life expectancy will rise to 12 years, in each of which the patient will enjoy full health. This is shown by the dashed line with HRQOL = 1.0 from time t to $(t + 12)$.

The QALY gain can be calculated by subtracting the total QALYs for an untreated patient from the total that they would have if treated. Without the treatment, the patient has 2 years at an average HRQOL of 0.6 = 1.4 QALYs, plus 8 years at an average of 0.45 = 3.6 QALYs, making a total of 5 QALYs. With the treatment, the patient has 12 years at full health, which is 12 QALYs. The gain is therefore 7 QALYs. Equivalently, we can calculate the total gain by summing the gains within each time period. The first 2 years have a HRQOL improvement from an average of 0.7 to 1 = 0.3, giving a QALY gain of 0.6. The next 8 years have an improvement from an average of 0.45 to 1 = 0.55, giving a QALY gain of 4.4. The final 2 years are additional years at full health, which is a gain of 2 QALYs. The total gain is as before 7 QALYs.

One of the big advantages of the QALY is that it can, in principle, be applied to any kind of intervention, whether it raises life expectancy without improving quality of life, improves quality of life without affecting longevity, improves both or improves one at the expense of lowering the other. However, to some people this is a weakness of QALYs, as they argue that length and quality of life cannot or should not be compared in the same metric.

Before looking at how QALYs are calculated in practice, it should be noted that if QALYs are gained, or indeed lost, at different times, then in principle they should be discounted if they are to be added together, in exactly the same way as costs, if they are to be used in an economic evaluation. There has been a considerable debate about this and there are arguments in favour of discounting both costs and QALYs at the same rate, discounting costs but not QALYs, and discounting them both, but at different rates.

In what follows, the concern is only with the quality of life element of the QALY, since the measurement of life expectancy has no special economic aspects attached to it except for discounting.

In carrying out an appraisal, QALYs can be calculated in a number of different ways. One is to measure the value that patients attach to their quality of life directly. Another is to apply a conversion factor to other indicators of health that will estimate from the indicator a quality of life value. However, an approach which has become most popular, and indeed is recommended by NICE, is to obtain from patients a measure of their health state using a generic health status measure, such as the EQ-5D (Brooks 1996; Herdman et al. 2011), and to apply to the resulting health profile data a value for each state that has been measured for a standard population. The intention is that those values should represent the values of society as a whole.

These sets of values are derived from population surveys. There are different techniques that are used to obtain values, of which the main four are rating or visual analogue scales (VAS), time trade-off (TTO), standard gamble (SG), and the DCE. A VAS usually consists of a single line drawn with verbal and numerical descriptors at each end, describing the meaning of the two ends, such as 'Best possible health' and 'Worst possible health'. Scale markers are often added to the line to denote distance along the line, and these are sometimes also numbered. Respondents are presented with a set of health states and are asked to rate the desirability of each by placing it at some point on the line on or between the two end points.

Fig. 6.6.3 Calculating gains in quality-adjusted life years.

In the TTO method, respondents are offered a choice between a number of years in full health and a number of years in a particular health state and asked to choose between them. Slightly different versions of this are used depending on whether the states are chronic or acute state and whether the respondent believes them to be better or worse than being dead. For a chronic health state preferred to death, different numbers of years in full health are offered for a fixed number of years in a health state, until the respondent cannot choose between the alternatives. The value for the health state is then determined by the ratio of the number of years in full health to the number of years in the health state. This calculation is based on the assumed equivalence of the number of QALYs generated by the two alternatives.

In the SG method, respondents are offered a choice between the certainty of being in a particular health state and a gamble whose outcomes are full health with a certain probability and death, and asked to choose between them. Again, slightly different versions of this are used depending on whether the states are chronic or acute and whether the respondent believes them to be better or worse than being dead. For a chronic health state preferred to death, different probabilities of being in full health are offered, until the respondent cannot choose between the alternatives. The value for the health state is equal to the probability at that point of indifference. This calculation is based on the *expected values* of the two alternatives, which is discussed later in the chapter (see 'Economic appraisal models and uncertainty').

DCEs applied to health state valuation are undertaken by offering respondents a choice between two, or sometimes more, health states and recording their choice. This technique does not measure any individual respondent's valuations of health states, but infers from the responses of a group their collective valuation.

Generic health state measures are usually accompanied by sets of values for each health state that they define. Because they have so many health states, the values are usually generated by a model, which may be called a *multiattribute utility model*, though that label is not explicitly used in some cases and its use in some cases may be disputed. Essentially, health states are decomposed into attributes. Generic health measures usually describe health states using different dimensions, in which people can be at different levels, which form the attributes.

The attributes are combined using a mathematical function. For example, the widely used EQ-5D has attached to it a number of value sets that have been calculated and published (Szende et al. 2007). The mathematical form used is additive, which means that the attributes are weighted and added together.

Measuring benefit in monetary terms

Monetary measures of benefits can be based on *revealed preference* or *stated preference*. Revealed preference techniques use observations from people's behaviour to infer monetary values. As an example, it is possible to examine the value that people place on the avoidance of death or injury by looking at the wages that are paid to people to undertake jobs that differ in the risk of these occurring but are otherwise identical. Stated preference techniques rely on surveys and experiments in which people are essentially asked what monetary value they place on healthcare, or health states or on other aspects of health benefits. They are not usually asked that question directly, but are given choices between different alternatives, from which money values are inferred.

Such stated preference studies are sometimes called *willingness-to-pay* studies, although that description is not entirely accurate for all of them. The economic theory underlying these kinds of studies is the measurement of what are called compensating variation and equivalent variation. In the context of measuring the money value of health benefits, these mean monetary payments made by or to a person to compensate for a change in their health, either an improvement or a deterioration, and *not* having a change in their health, respectively. Willingness to pay refers to compensation paid *by* the person, either for obtaining an improvement in their health or not having their health deteriorate. Willingness to accept refers to compensation paid *to* the person, either for having their health deteriorate or not obtaining an improvement in their health.

Although stated preference methods used vary, best practice in economics more generally is to use the *contingent valuation* method. Contingent valuation requires the survey or experiment to describe a plausible market in which the choices made by respondents about goods reveal the values that are required. The values are said to be contingent on that description. One way to do this is to use a DCE in which price is one of the attributes that the goods have.

Economic appraisal models and uncertainty

In theory, it is possible that an EA could be carried out using one source of data, for example, a clinical trial in which resource use, costs, and quality of life are all measured for individual patients. This would have all of the advantages of a clinical trial in terms of the reliability of results. In practice, EAs are usually based on different sources of data, which have to be linked together. There are many calculations behind the estimates of costs and benefits, which are embodied in what is called an *EA model*, and in practice all healthcare EAs involve some modelling. In fact, economic modelling is regarded by many as superior to a trial-based EA as it may overcome the problems that trials have in terms of generalizability and speed of producing usable results. Of course, models may use data from trials, but only as one input.

A simple model might be regarded simply as a balance sheet in which the data used to calculate costs and benefits are combined to give figures for total costs and total benefits. However, many EAs cannot use such simple models, and these are no longer regarded as acceptable in the context of technology appraisals examined by bodies such as NICE. The reasons are, first, that treatment options are not always straightforward and clinical decision-making may involve strategies for management, rather than a simple choice between using and not using a single therapy; and secondly, that there is usually some uncertainty about both the model and the data.

As a result, modelling usually uses *decision analysis* (see, e.g. Briggs et al. 2006). This deals both with the complexity issue, by imposing a structure on the implied clinical decision-making, and some aspects of uncertainty. However, there is one aspect of uncertainty that is not dealt with directly by decision analysis, which is uncertainty about the values that data take. A number of techniques have been developed in recent years to deal with this, which are briefly described.

The problem that is dealt with can be encapsulated by the observation that summaries of effectiveness data, such as changes in

blood pressure resulting from some intervention, are usually presented as both a point estimate and an interval estimate, or confidence interval, reflecting variability in the data; we should have a similar summary for cost-effectiveness data. When this is done as part of a trial-based analysis it is called *stochastic CEA*. Unfortunately, there are two problems with this. First, many of the data used in an EA model are not based on sampling, and therefore do not have a variance that can be used to create an interval estimate. Secondly, the summary index of cost-effectiveness is the ICER, which as a ratio has special problems, such that in general it is not possible to estimate a confidence interval even if all of the data that are used to calculate it do have variability. This second problem applies equally to trial-based and model based EAs.

Sensitivity analysis

The usual way in which uncertainty is dealt with when using a model is *sensitivity analysis*. This is a set of techniques that analyse how sensitive the results are to changes in the model, for example, in the data that are contained within it or the way that the data are combined. Some sensitivity analysis techniques are described below. In these, the model that has the best assumed structure and data is called the *base case*, and the assumptions and data that we wish to test are referred to as the *parameters* of the model.

One-way sensitivity analysis means looking at how sensitive results are to changes in one parameter. If, for example, a new screening programme is appraised using a model, one of the parameters of the model may be the unit cost of the test used. The base case will use the best estimate that the analyst has of the unit cost as an input to the calculated ICER. One-way sensitivity analysis will calculate the ICER for different values of the unit costs, showing whether the cost makes a lot of or a little difference to the result.

Of course, what is meant by a lot or a little should really be defined. One way to do this is to use the ceiling ratio. If at every possible value of the parameter the ICER remains above or alternatively remains below the ceiling ratio, then the result remains the same, and the decision is not sensitive to the value of the uncertain parameter. In other cases, it may be that at some levels of the parameter for example when the unit cost is low—the ICER will be below the ceiling ratio, but at others—for example, when the unit cost is high the ICER will be above. At some point the ICER will be equal to the ceiling ratio, and at that point called a threshold—a change in the preferred option occurs. This is known as threshold analysis. If the base case and the threshold are very different, then the results are not sensitive to the values of the parameter.

But again, what does very different mean? One way to deal with this is to define upper and lower plausible values for the parameter; for example, with a base case cost of £100 per unit, it may be thought unlikely that the cost could be as high as £200 or as low as £10. This will give a plausible range to the calculated ICER, and if the threshold is within that range, then the results are sensitive to the assumption made.

This can be extended to vary more than one parameter at the same time and to observe the combined impact on the ICER. The ceiling ratio can again be used to define a threshold, and plausible ranges for the ICER can be calculated from the plausible values of the variables, taken in combination. Such multiway analysis is essential, because it is possible that separate one-way analyses of the parameters might suggest that the results are not sensitive to their value, but in combination they might be.

Statistical sensitivity analysis

Plausible range methods are not very satisfactory because their basis is often unclear and not testable. Using statistical methods is better because, as suggested, the base case cost-effectiveness results can be seen as a point estimate and sensitivity analysis as an interval estimate. When this is done as part of a decision analysis model, it is called *probabilistic sensitivity analysis*.

In this, Monte Carlo simulations are used to generate an ICER distribution. A distribution for each of the model's parameters is assumed, if it is not known. Samples are taken from each distribution, and the ICER is calculated from those simulated data using the model. This is repeated many times to generate an ICER distribution, from which, in principle, a variance might be calculated, and therefore a confidence interval.

Unfortunately, in practice that might still not be possible, because of another problem with ICERs. It is quite possible that the distribution of the ICERs generated by simulation might include both positive and negative values. These mean such different things—a negative value means dominance rather than a true ICER—that a confidence interval calculated from them is meaningless.

There are two possible solutions to this. One is essentially to get rid of the ICER by using the net benefit approach described earlier. Because net benefit is a single number, not a ratio, there is no problem with using simulation to generate a distribution of it and to calculate a variance and therefore an interval estimate.

Another solution is to generate a *cost-effectiveness acceptability curve* (CEAC), which retains the CER, but uses a method of describing uncertainty which is different to the confidence interval (van Hout et al. 1994). The simulated ICER values are each compared with a ceiling ratio, and a count is obtained of the proportion of simulated values that are acceptable at that ratio. This is repeated for each possible value of the ceiling ratio, and the proportion that is acceptable will be different for each of those values. A CEAC plots these together, as in Fig. 6.6.4. In this illustrative example, the proportion 25 per cent of the simulations of cost and outcomes for a particular therapy are acceptable if the ceiling ratio is £4500 per QALY gained; 50 per cent if £11,500 and

Fig. 6.6.4 Cost-effectiveness acceptability curve.

75 per cent if £20,500. At the ceiling ratio £30,000, 89 per cent are acceptable. Under certain conditions, which are beyond the scope of this chapter to describe, the proportions may be interpreted using a Bayesian approach as probabilities, such that at a ceiling ratio of £30,000, there is a 0.89 probability that the therapy is cost-effective.

Decision analysis

Decision analysis is used when the outcomes of decisions are not certain, but the probabilities of different outcomes are known. For example, the treatment of cases detected by a screening programme may not be effective in every case, but is known to work in 80 per cent of cases. It is of particular value when decisions involve strategies with different actions. For example, if some members of the population do not respond to a whole population screening initiative, then they may be targeted to increase uptake. Decision analysis is a way of structuring the different options in order to calculate which of the strategies is best.

Decision analysis relies on the concept of *expected values*. We can think of the expected value of something as its average value when it is repeated a large number of times. For example, if a treatment produces a gain of 2 QALYs per person in 80 per cent of cases and a gain of 1 QALY per person in the remaining 20 per cent, then out of 100 patients the total gain will be $(2 \times 80) + (1 \times 20) = 180$, giving an average of 1.8 QALYs gained per patient. This is the expected value. Of course, in reality the nature of uncertainty is such that it is unlikely that the probabilities of 0.8 and 0.2 would produce exactly 80 and 20 in a population of 100, which is why an assumption of large numbers is made. More generally, the expected value is calculated as the sum over all possible outcomes of the probability of the outcome multiplied by the value of the outcome.

Decision analysis calculates the expected values of both costs and benefits and also, though this is a more complicated issue, ICERs. It usually takes the following form, which may be compared with the more general formulation of an EA given earlier:

1. Structure the problem by constructing a mathematical model of decision-making, usually a decision tree. Identify the decision alternatives; list the possible outcomes of each alternative; and specify the sequence of events.
2. Assign probabilities to chance events.
3. Assign values to all possible outcomes of chance events.
4. Calculate the expected value of each strategy.
5. Perform sensitivity analyses by systematically changing the assumptions in (1)–(3) to see the impact on the result of (4).

An extension of decision analysis, which is however not yet well-established in practical decision-making, is *value of information analysis*. Decision analysis is based on choosing the alternative that has the highest expected value given current information. The value of information approach analyses the consequences of making the wrong choice with the aim of assessing how much it is worth spending to improve information so that we do not make the wrong choice. If an incorrect choice is made, the loss incurred is the outcome from the option chosen minus the expected value of the best alternative option. Multiplying this loss by the probability that the incorrect option is chosen gives its expected value.

This gives the *value of perfect information*; it is worth paying up to this value to avoid making the incorrect choice and therefore investing in research into probabilities of events, quality of life, and costs. Using statistical information on levels of significance and power, it is also possible to estimate the *value of sample information*, which gives the amount that it is worth paying for a sample of given size to improve information.

Economic appraisal and equity

In discussing equity, we noted that Culyer and Bombard (2012) have suggested using a checklist to ensure that decision-makers take all aspects of equity into account. Here we describe only a narrow range of equity analyses, related to EAs and concerning the distribution of healthcare resources and outcomes between people.

The impact of healthcare interventions is ultimately on individual people, and it is always relevant to examine equity at that level. However, in practice inequities are mostly observed between population groups defined by particular characteristics, for example, people who have serious ill health or are poor, aged, or children. This is particularly important for public health interventions, which are usually conducted at the population level.

Similarly, although it is always relevant to look at the distributional consequences of decisions about every kind of healthcare, it may be of particular importance for public health interventions, since they may be designed specifically to reduce inequalities in population health. It may be that some interventions that target individuals or groups who are disadvantaged would not be regarded as cost-effective relative to many other interventions. It may also be that some public health interventions, such as those designed to enhance health-promoting lifestyles, may be less effective for those who are disadvantaged, thereby increasing health inequalities. In each case an analysis of the implied trade-off between efficiency and equity is essential.

Despite the near-universal acceptance that assessment of equity is as important as efficiency in EA, this has not been matched by practice. In a systematic review, Sassi et al. (2001) were unable to find any satisfactory equity analyses as part of EAs of healthcare in general; Weatherly et al. (2009) found the same for public health interventions.

Cookson et al. (2009) proposed four possible approaches to analysing equity:

1. Reviewing existing inequalities related to the topic being appraised. This is not in itself evaluative, but it provides background information and therefore some context to decision-making that is based on an efficiency-oriented EA.
2. Measuring the redistributive impact of a decision about healthcare, that is a quantitative description of who gains and who loses, and the size of gains and losses. Baeten et al. (2010) proposed that for interventions targeted on a particular group, appraisal might assess outcomes in absolute terms for the targeted group but also relative to groups who are not targeted. Sassi et al. (2001) made similar suggestions for assessing the distributional effects for subgroups: the effect of competing interventions; the effect of selectivity; and the effect of prioritizing over other interventions.

3. If an intervention generates greater equity, but at the expense of a larger health gain overall, measuring its opportunity cost. This cost is not measured in terms of money, but of health, for example, the number of QALYs that would be lost for the population overall by targeting a particular group.
4. Cost-effectiveness with equity weights applied to the outcomes for different groups. An example which is in practice applied is the 'end-of-life premium' used by NICE in England, which weights more highly QALYs generated by interventions where survival without the intervention is short, even if the length of the gain from the intervention is itself short. Baeten et al. (2010) also proposed a variant of this in the form of multi-criteria decision analysis (MCDA). In MCDA, decision-makers consider many relevant characteristics of an intervention and explicitly incorporate trade-offs within and between them in the form of relative weights. The proposal is that both efficiency and equity consequences are included in characteristics of intervention, thereby taking both into account. Unlike the other three proposed approaches, explicit weighting requires an extra source of data to generate the weights, rather than using data available from an efficiency-based appraisal.

Baeten et al. (2010) illustrated their proposal with an assessment of equity for breast cancer screening. They applied the redistributive impact assessment and both variants of the equity weighting approach; these gave very similar conclusions in favour of selectivity on both efficiency and equity grounds.

Economic appraisal of public health interventions

This chapter has highlighted some issues that arise in applying EA to specifically public health interventions. The state of the art in addressing these is currently less advanced than for other healthcare programmes. But there are many examples that demonstrate both the value of EA in public health and the value of public health interventions themselves.

In reviewing the state of the art in EA of public health interventions, Weatherly et al. (2009) outlined four key methodological challenges, one of which, the specific concern that public health has for equity, we have already discussed. Of the others, one is the kind of evidence that public health interventions are based on. Guidelines for HTA of interventions with individual patients emphasize that the best source of scientific data is the randomized controlled trial (RCT). However, not only are there fewer RCTs for public health interventions, they are inherently more difficult to conduct. We discussed one of the reasons for this in relation to discounting (see 'Measuring costs'); the impact of public health interventions may be on a longer time scale than an RCT could plausibly encompass. Other problems include that it may be infeasible to establish controls for population-based interventions such as screening and that pathways of causation between intervention and outcome are often less direct than individual treatments, for example, health education programmes. It is therefore necessary to use other ways of establishing evidence, and to rely on extensive use of modelling.

A second concerns the way in which outcomes are specified and measured. Cost-effectiveness analyses use QALYs or other health measures as their outcome measure and it is arguable that

is the correct measure where health gain to individual patients are the main aim. However, in public health interventions not only is health gain difficult to measure, because of the difficulties of establishing evidence that we have discussed, but also because the intervention may have additional goals, or important side effects. These include improving public knowledge and awareness, and the benefit of reassurance, as well as possible unintended adverse consequences such as false reassurance and raised anxiety over possible health problems.

The third concerns the boundaries given to the costs and benefits that are included in an EA. Previously we stated that a social perspective would include all of these (see 'Social costs and benefits'), whatever they are and whoever bears them, but it may be essential to restrict their scope depending on the perspective that is taken. For example, as our discussion of the NICE threshold implies (see 'Cost-utility analysis'), an HTA for interventions that are paid for by a health agency that has a fixed budget is justified in restricting the scope of costs to those incurred by that agency. However, public health interventions typically have much wider effects on the public sector than the health sector, and indeed on the economy as a whole. In turn, those could impact on health; Weatherly et al. (2009) suggest as an example that 'improvements in housing could reduce illness and injuries, with consequent reductions in health care utilization'.

Despite these problems, there are reasons to be optimistic both about the possibilities of undertaking EA in public health and also about the results from such analyses. Owen et al. (2011) examined the economic analyses that formed the evidence base for public health guidance by NICE issued from 2006 and 2010, an example of which is described in Box 6.6.2. Of 200 cost-effectiveness analyses, 30 of the interventions both improved outcomes and lowered costs, in other words dominated the alternative and were in the south-east quadrant of the cost-effectiveness plane. One hundred and forty-one had cost-effectiveness ratios below NICE's official stated 'lower threshold' of £20,000 per QALY gained, with a median of £1,020; a further seven were below the 'upper threshold' of £30,000, with a median of £25,150; and 11 were above that, with a median of £90,786. Eleven were dominated, that is in the north-west quadrant where costs are higher and benefits lower.

Of course, this sample is only from England, and the coverage may not be representative of the broad range of public health interventions; 127 of them were related to smoking and other interventions may not have been selected for evaluation if they were considered unlikely to be cost-effective. Nevertheless, they did cover very different types of interventions to very different sections of the population. One finding was that interventions aimed at the population as a whole produced the lowest costs per QALY gained.

Efficiency and equity in the economics sense are not the only considerations for decisions in public health or healthcare in general, and EA is only one of the types of evidence that are relevant to them. However, EA is a powerful way of assessing evidence about important consequences of such decisions, and in particular helps in considering how to manage scarce healthcare resources. In advocating that public health should receive a fair share of those resources, it is essential to base arguments that are as strong as those for other types of healthcare and to use equally powerful techniques for analysing them.

Box 6.6.2 Economic analysis of interventions to prevent smoking among schoolchildren

An example is the evidence review underlying NICE guidance on public health interventions to prevent the uptake of smoking among schoolchildren (Jit et al. 2009). A literature review was undertaken and no published economic evaluations of school-based smoking prevention programmes in the United Kingdom were identified. It was argued that studies based in other countries were of limited relevance to the United Kingdom because of differences in the populations being studied and the methodological framework used. In addition, most studies assumed that school-based smoking prevention programmes achieved a lasting reduction in smoking prevalence beyond school age, and this finding was not supported by evidence used to produce the guidance. As a consequence, the authors undertook new research to evaluate whether or not the implementation of a school-based smoking prevention initiative would be cost-effective.

Survey data were used to quantify the association between the age at which smoking was initiated and the probability of quitting smoking quit in later life (older age at initiation was significantly associated with an increased likelihood of quitting in later life). A systematic review was undertaken to quantify the impact of smoking prevention programmes on decreasing smoking uptake in the long term and delaying the onset of smoking, and whether these effects varied by the age of the participants.

These data were combined with cost and other data in an economic model and used to calculate the cost-effectiveness of school-based smoking prevention programmes. Results were presented for a generic programme delivered to 11-year-old students. Assuming an intervention cost of £38.50 per participant the CQG was estimated to be £2030–12,700, depending on assumptions made about the persistence of effect of the programme over time. The results were fairly robust to changes in key model parameters concerning the association between age of smoking initiation and probability of smoking in later life, mortality in smokers and non-smokers, health-related quality of life in smokers, lifetime medical costs of smokers, and the quality of the studies used to inform the models. In few cases was the extra CQG greater than the ceiling ratio, which was assumed to be £20,000 per QALY gained.

Behavioural economics and health

Judd B. Kessler and C. Yiwei Zhang

Introduction to behavioural economics and health

Behavioural economics is a field at the intersection of economics and psychology. Standard economic theory is built on the assumption that individuals are fully rational, completely selfish, forward-thinking decision-makers. This set of assumptions has allowed economists to predict behaviour using simple and tractable analytical models. But research from both economics and psychology has demonstrated that individuals regularly deviate from the predictions of standard economic theory and do so in systematic ways. Behavioural economics aims to: (1) explain why individuals deviate from the assumptions of standard economic theory and (2) use these insights to advance our models of individual behaviour.

By improving our models, behavioural economics allows policymakers to design interventions—like the health interventions that are described in this chapter—to more effectively achieve policy goals. In this way, behavioural economics is both descriptive, giving us a better picture of what behaviour looks like (and why it looks that way), and prescriptive, suggesting how policy can most effectively impact individual decision-making.

In this chapter, we discuss four major topic areas within economics and behavioural economics: (1) reward incentives, (2) information and salience, (3) context and framing, and (4) social forces. We will address each topic area with a section of the chapter. Within each section, we will highlight some of the topic area's most influential papers—including some from outside the health domain, which we believe provide relevant background.

Throughout the chapter, we describe research on a number of important health behaviours, including: medication adherence, obesity and weight control, and medical donation. While we touch on a number of other health behaviours in the chapter, we describe these three (and the reasons we find them of particular interest) in the following section.

It is worth noting that this chapter is by no means exhaustive in its coverage of the behavioural economics insights that might influence health behaviours or of the health behaviours that might be subject to the insights we discuss. Instead, we have picked a few illustrative settings where we have seen fruitful application of behavioural economics research and expect to see more in the coming years.

Externalities

Since many papers described in this chapter analyse interventions that affect health behaviours, it is worth outlining in broad

strokes what standard economic theory says about when policymakers should be intervening in the health domain. This exercise provides a baseline for thinking through the additional policy interventions that might be justified by results from behavioural economics.

As already noted, standard economic theory models individuals as fully rational, selfish, and forward thinking. Individuals who satisfy these assumptions (who we simply call 'rational' throughout) are usually better off when left to their own devices. If a rational individual fails to take his doctor-prescribed medication, his decision is likely best for him, since by assumption he has thought through all the costs and benefits and decided that the costs (e.g. the cost of purchasing his medication and the pain of the side effects) outweigh the potential benefits (e.g. his lower risk of a heart attack).

Under the assumption that individuals are rational, there are generally only two reasons for intervention. First, if the rational individual suffers from a constraint that prevents him from implementing his preferred choice (e.g. he cannot afford to purchase his medication even though he would like to take it) then a policymaker may want to help the individual by loosening those constraints (e.g. providing him with a loan to help pay for his medication). Second, a policymaker may want to intervene if a decision creates *externalities*. Externalities are indirect effects on other agents that an individual does not fully consider when making his decisions. For example, if the patient in the earlier example cannot afford his cost of care for his heart attack, then when he fails to take his medication he forces society (i.e. the government and thus all tax payers) to cover some of his higher costs. Consequently, his decision about whether or not to take his medication affects people beside himself. That individuals fail to consider the costs imposed on other agents (or the benefits incurred by other agents) generally leads to socially inefficient outcomes.

Externalities are the key rationale for policy interventions across a number of domains both inside and outside of health. The government taxes pollution created by companies and individuals since pollution imposes negative externalities on those exposed to it. Regulation that forbids individuals from blasting music at 3 a.m. is designed to discourage the negative externality a rowdy party might have on neighbours who want to go to sleep.

As hinted above, a number of activities in the health domain create externalities. Some of the externalities are obvious while others are not. On the obvious end of the spectrum, medical donations (e.g. donations of blood, bone marrow, tissues, and organs)

create positive externalities since they clearly benefit other people. Individuals who receive donor kidneys can expect better health outcomes than if they remained on dialysis. Some forms of preventative care are both beneficial to the recipient and create positive externalities for the health of other people. Receiving a flu shot or a vaccine helps keep the recipient from getting sick but also plays an important role in preventing the spread of disease since inoculated individuals are less likely to spread a virus. At the less obvious end of the spectrum, many activities that make a person healthier (e.g. healthy eating, exercise, medication adherence, and smoking cessation) can generate positive externalities for society since most individuals do not pay the full cost of their medical care and are instead covered in part by health insurance, the government, or a combination of the two. Consequently, requiring less care or staying healthy for longer (and requiring care later in life) makes the individual better off and lessens the cost paid by others in insurance premiums and taxes.

Given that many health activities have positive externalities, it may be socially beneficial to encourage individuals to engage in them. Economics and behavioural economics can provide strategies to most effectively encourage people to eat healthy, take their medication, donate their organs, get flu shots, and so on.

Behavioural biases

When rational individuals do not face constraints that restrict their choice and do not impose externalities with their actions, then there is little scope for intervention, even if we disagree with individuals' choices. An individual who can afford his medication and pays for all his health costs out of pocket may choose not to take his medication because he simply prefers not to. If he is fully informed about the costs and benefits and he is rational, we can do no better than to trust his judgement.

Behavioural economics has demonstrated, however, that individuals are not fully rational in the way standard economic theory predicts. Individuals who are not fully rational (who we will call 'behavioural') might suffer from biases that make it difficult for them to achieve the behaviour they actually prefer. This introduces another rationale for intervention: helping individuals achieve their own desired behaviour.

For example, one way in which behavioural individuals may make suboptimal choices is by displaying *present bias*. In particular, individuals often overweight costs and benefits incurred today (i.e. the present) relative to the costs and benefits incurred tomorrow (i.e. the future). This type of bias can lead individuals to forgo healthy behaviours and do so in a way that is inconsistent across time. Imagine an individual deciding whether to go to the gym, which has a cost today in terms of time and fatigue but has health benefits in the future. When considering his choice today, he may overweight the time and fatigue costs—since they are incurred in the present—and so decide to skip the gym. When considering his choice for tomorrow, however, he would not overweight those costs. When considering tomorrow, he may prefer to go to the gym and even believe that he will do so. When tomorrow arrives, however, it has become the present, and he again overweights the time and fatigue costs and again skips the workout.

This inconsistent behaviour is not unique to going to the gym. It can explain why individuals procrastinate about eating healthily, quitting smoking, or getting a flu shot. Each of these activities features a present cost (e.g. sacrificing something you enjoy, giving

up time, incurring physical discomfort) and a delayed benefit (e.g. better health) and so individuals might perpetually wait to incur those costs until a never-arriving tomorrow. If our patient from the medication example described earlier was present biased, he might skip taking his pill because he overweights the small costs he faces today like paying for the prescription and experiencing side effects. We consider these examples mistakes because if the behavioural agent could commit today to force himself to go to the gym (or eat the apple, or quit smoking, or get the flu shot, or take his pill) tomorrow, he would choose to do so. Behavioural individuals may want help making choices and following through with them.

Present bias is just one of many behavioural phenomena that might make individuals deviate from their own desired behaviour. For example, a behavioural individual might forget to take his medication, which a rational agent would not do. A behavioural individual might not attend to all the relevant data needed to make an informed decision about whether to take the pill or might fail to aggregate the data he does consider.

Behavioural economics can help identify cases where individuals might have trouble (e.g. due to present bias or forgetfulness) and suggest strategies to help individuals achieve their ideal behaviours (e.g. commitment contracts or reminders, discussed later in the chapter). As we go through each topic area, we will describe the way individual behaviour differs from the predictions of standard economic theory. We will then describe interventions—suggested by economics and behavioural economics—that can encourage individuals to improve their own decision-making and generate better health outcomes for the decision-maker and better outcomes for society at large.

Health behaviours

Here we highlight three health behaviours that we reference repeatedly throughout the chapter. We think these behaviours are of particular interest for interventions motivated by behavioural economics.

Medication adherence

The failure of individuals to properly adhere to medication regimens prescribed by their doctors is a major issue in healthcare. Non-adherence can often lead to serious health consequences as well as increased healthcare costs down the road. Estimates from Osterberg and Blaschke (2005) suggest that around half of all medication-related hospital admissions in the United States are a result of failure to adhere properly to medication. These hospital admissions are estimated to cost approximately \$100 billion a year. While medication expense may be part of the explanation, non-adherence is a problem even among patients who face zero co-pays and so can get their medication for free (see Doshi et al. 2009). Cutler and Everett (2010) suggest various reasons why people fail to adhere to medication including: lifestyle, psychological issues, health literacy, support systems, and side effects. Behavioural economics interventions that help individuals overcome some of the common barriers to adherence can generate better health outcomes and lower cost of care.

Obesity and weight control

Obesity is a major problem in healthcare and is blamed for over 110,000 deaths a year in the United States alone (Flegal et al.

2007). Flegal et al. (2010) calculate that 68 per cent of Americans are overweight or obese. Schroeder (2007) suggests that decreasing obesity—along with decreasing smoking—can lead to substantial improvements in the state of health in the United States. Individuals often have trouble controlling their weight. DellaVigna and Malmendier (2006) find that individuals buy expensive monthly gym memberships but go so infrequently that paying per visit would cost less. This result suggests that individuals have trouble making it to the gym even though they want to and intend to go. Behavioural economics can help explain the difficulty individuals have in sticking to a weight-loss regimen and can provide strategies or interventions to help people succeed.

Medical donation

There are a number of forms of medical donation, including blood and plasma donation, bone marrow donation, and organ and tissue donation. Medical donation is an important area of health research since these donations can have a substantial impact on health outcomes (Schnitzler et al. 2005a, 2005b) and cost of care (Dew et al. 1997) and there is often significant need. As of July 2014 over 123,000 individuals in the United States were on the waiting list for an organ transplant (United Network for Organ Sharing n.d.). Registered organ donors make their organs available for transplant upon their death, and one deceased donor can provide up to eight life-saving organs. However, fewer than 50 per cent of Americans over the age of 18 are registered as organ donors (Donate Life America 2014). Behavioural economics interventions may be particularly relevant in motivating medical donation since monetary incentives are often not allowed in medical donation (Roth 2007).

Reward incentives

Reward incentives are a natural place to start an investigation of how economic and behavioural economic forces impact health behaviours. Reward incentives show how traditional economic interventions work and how these interventions can be improved by insights from behavioural economics.

In standard economic theory, individuals value money and other tangible rewards and engage in effort to get them. People go to work to earn money and we expect them to work harder when there is more money at stake. Consequently, standard economic theory suggests that reward incentives—particularly monetary incentives—can motivate individuals to engage in behaviours that they otherwise would avoid. We begin this section by describing interventions that utilize standard reward incentives in the health domain.

Behavioural economics has made two important advances with regard to reward incentives and how they affect behaviour. First, it has suggested that not all incentives are created equal. Individuals overweight small probability events and feel losses more severely than equivalent gains. A reward incentive that leverages these biases might be more effective for the same expected value. Second, and much more troubling for standard economic theory, behavioural economics has shown that in certain domains individuals respond in perverse ways to reward incentives. In some settings, monetary incentives lead individuals to respond with *less* effort rather than more.

After describing settings where standard reward incentives motivate health behaviours, we catalogue examples of

interventions that leverage behavioural biases in designing reward incentives. Finally, we describe settings where reward incentives backfire.

Standard reward incentives

There are a number of health domains where standard reward incentives have been shown to successfully influence health behaviours. Here we highlight their use in three domains: obesity and weight control, smoking cessation, and medical donation.

In the context of obesity and weight control, researchers have used monetary and non-monetary incentives to encourage more frequent gym attendance. Charness and Gneezy (2009) report the results of two such studies on incentives and gym attendance. In the first study, they compare the gym attendance of three groups of college students participating in a randomized experiment. One group was provided only with information regarding the value of exercise. A second group was provided with the same information and received an additional \$25 if they visited the gym once in the following week. A third group was treated like the second group but received an additional \$100 if they visited the gym eight more times in the following 4 weeks. The authors find that individuals respond to monetary incentives. Those who were paid to go to the gym were much more likely to do so, and those who were paid for more visits went more often. The second study took a similar form but included biometric measures to better gauge health improvements. The study found that individuals paid to go to the gym more often had lower body fat, lower body mass index, and improved on a number of other health measures. The authors provide evidence that the effects from both studies persist; those who were paid to go to the gym continued to do so at higher rates for a few months after the incentives were removed. This result suggests that these individuals may have formed a habit of gym attendance. As will be seen throughout this section, this potential habit formation is quite rare in the context of reward incentives.

A similar study by Acland and Levy (2013) also finds that individuals were more likely to go to the gym when paid to do so. They also observe that the effect persists in the weeks after the incentive was removed. After a semester break, however, the group that had seemed to form a habit for gym attendance was no longer more likely to attend, suggesting that the habit was short-lived.

In the context of smoking cessation, Volpp et al. (2009) report the results from an experiment at a multinational company. Half of the employees in their sample were given information about smoking cessation programmes while the other half received the same information plus incentives worth a total of \$750 for enrolling in a programme, quitting smoking within 6 months, and staying quit for an additional 6 months. Individuals with the incentives were significantly more likely to complete the programme, quit, and stay quit.

In the context of medical donation, the use of monetary incentives is often restricted. For example, the National Organ Transplant Act of 1984 prohibits the use of ‘valuable consideration’ to induce organ donation. Fortunately, standard economic theory does not require that reward incentives be monetary for them to be effective. In the context of medical donation, a variety of non-monetary reward incentives have been shown to generate increased willingness to donate.

Individuals are more likely to donate blood when provided with coupons for merchandise (Ferrari et al. 1985), lottery tickets

(Goette and Stutzer 2008), and other incentives (for a summary of blood donation incentives, see Goette et al. (2010)). Lacetera et al. (2012) do an extensive empirical analysis of participation in American Red Cross blood drives and find that drives with non-monetary incentives for blood donation (including blankets, T-shirts, mugs, and coupons to retailers) generate more donors. In addition, the larger the economic value of the incentive, the bigger the increase in donors. They caution, however, that some of the increase in donation may be the result of substitution away from nearby drives that do not have incentives. A review of a variety of blood donation research supports the claim that incentives increase blood donation without affecting quality (Lacetera et al. 2013). Related work has demonstrated that individuals are more likely to become bone marrow donors when legislation that provides donors with paid leave and tax incentives is in place (Lacetera et al. 2014).

A particular non-monetary incentive that might motivate individuals to register as organ donors is priority on organ donation waiting lists for those who register but end up needing organs rather than being in a position to provide them. This non-monetary incentive—a higher likelihood of receiving a transplantable organ or receiving a transplantable organ more quickly—can be given to registered donors simply by changing the way organs are allocated. Both Israel and Singapore currently provide priority on organ donor waiting lists to registered donors. Kessler and Roth (2012) investigate the effect of a priority rule on a laboratory game designed to look like organ donor registration and show that it substantially increases the likelihood of donation.

Early data from Israel, which implemented the policy fully in 2012, suggests that the policy may have increased the number of deceased organ donors and the organ donation rate (Lavee et al. 2013). One quirk of the Israeli policy, however, is that it has the potential for a loophole that allows individuals to receive priority without ever being in a position to donate their organs. A follow-up study (Kessler and Roth 2014a) investigates the effect of a loophole and finds that in a laboratory setting, such a loophole can eliminate the beneficial effect of the priority rule. Allowing individuals to receive the priority without paying the costs of donation completely eliminates the effectiveness of the priority rule. In addition, when subjects receive feedback about the use of the loophole they become less likely to register as donors than when no priority system is available, suggesting that how these priority systems are implemented can be crucial to their success.

Designing incentives using behavioural economics

As noted earlier, behavioural economics has shown that individuals overweight small probability events, feel losses more severely than equivalent gains (called *loss aversion*, see Kahneman and Tversky (1979)), and do not like to feel regret (called *regret aversion*).

Lotteries can take advantage of the fact that individuals overweight small probability events. For example, providing a 1 per cent chance of winning \$100 might motivate people more substantially than offering them \$1 directly, even though the two have the same expected value.

Combining probability weighting with loss aversion and regret aversion, some studies have motivated individuals to take health actions using *regret lotteries*. In a regret lottery, all individuals are

entered into the lottery and informed about whether their name is picked. If an individual fails to take a required action, however, she fails to earn the lottery prize when picked. Even if a 1 per cent chance of winning \$100 is not enough to motivate an individual to take an action (e.g. going to the gym today), she might go to the gym to avoid the potential distress of knowing she would have won \$100 but lost it by skipping her workout. The regret lottery leverages overweighting of small probabilities through the lottery, loss aversion by framing the earnings as money that is lost, and regret aversion since it threatens individuals who fail to take the rewarded action with feelings of regret.

Regret lotteries have successfully influenced behaviour in a variety of health domains. In the context of medication adherence, Volpp et al. (2008) find that providing a regret lottery worth either \$3 or \$5 in expected value significantly increases the likelihood that individuals correctly take their prescribed medications. In the context of weight loss, Volpp et al. (2008) find that subjects lose significantly more weight when provided with a regret lottery that pays out an expected \$3 per day (in the form of a 20 per cent chance of winning \$10 plus a 1 per cent chance of winning \$100) if the subject is on track to his or her weight loss goal.

Another way to leverage loss aversion with monetary incentives is to provide individuals the opportunity to make *commitment contracts* (also called *deposit contracts*) in which they put up their own money. This money is then forfeited if they fail to achieve a certain goal, such as reaching a weight loss target or attending the gym a specified number of times in a week or month. This strategy allows individuals to create monetary incentives for themselves and leverage loss aversion simultaneously. Volpp et al. (2008) also find that a commitment contract (in which committed funds were matched one to one by researchers to increase take up) was effective at achieving weight lost by study participants.

One concern with monetary incentives of any form is that they may generate short-term effects. Once the monetary incentives are removed, individuals may backslide into their unhealthy behaviours. In Volpp et al. (2008) once the regret lottery or commitment contract was removed, both groups regained a significant amount of the weight they had lost during the study. John et al. (2011) run a longer study in which some subjects have a commitment contract to lose weight (also with a one-to-one match) for a period of 24 weeks. They find that subjects with the commitment contract lose significantly more weight but much of the weight is regained in the 8 weeks after the incentive is removed. At the end of those 8 weeks, the weight of the group that previously had the contract was no different from the control group that never had the contract.

On the other hand, Giné et al. (2010) find that the effects of a 6-month commitment contract on smoking cessation can persist over the long run. In particular, they find that smokers who were randomly offered the contract were significantly more likely to pass a urine test for nicotine and cotinine (by-products of tobacco use), and they remained significantly more likely to pass another (surprise) urine test administered 6 months after the removal of the incentive. Examples of behavioural economics in action are given in Box 6.7.1.

There are other ways in which incentives can be altered to take advantage of forces uncovered by behavioural economics. One example is to bundle something desirable (or addictive) with a behaviour you want to encourage. The old adage ‘a spoonful of

Box 6.7.1 Behavioural economics in action**Behavioural Insights Team (BIT)**

Established in 2010 by UK Prime Minister David Cameron, the BIT (nicknamed the ‘Nudge Unit’) uses insights from behavioural economics and psychology in developing and testing different public policy measures. For example, inspired in part by Giné et al. (2010), the BIT is considering using loss-aversion and commitment contracts in their countrywide efforts to reduce smoking (BIT 2010).

StickK.com

The brainchild of several economists, StickK.com is a website that allows individuals to create and enter into their own commitment contracts to help them achieve personal goals. Common personal goals include losing weight, exercising regularly, and quitting smoking. Individuals determine how much money, if any, to put at stake and designate another individual to verify the goal outcome. Should an individual fail to reach his or her goal, the forfeited money goes to a charity of their choice or to an ‘anti-charity’ that the individual does not want to support, making failure to meet the commitment feel even more costly.

sugar helps the medicine go down’ can help explain why some vitamins are candy-coated. In this spirit, Milkman et al. (2014) developed an incentive for gym attendance using an activity that they deemed to be desirable and possibly addictive. In their study, researchers provided each subject in their treatment groups with a loaner-iPod loaded with popular books-on-tape that were considered relatively addictive (e.g. *The Hunger Games* and *The Da Vinci Code*). For one treatment group, the iPods were stored in lockers at the gym and could only be accessed if the subject was at the gym. The authors found a significant increase in gym attendance in this group over the control group, but also found that the effect deteriorated over time.

Crowding out

Researchers in a number of disciplines across the social sciences have uncovered some perverse effects of incentives. In particular, financial incentives have been shown at times to decrease effort rather than increase it. This phenomenon has been called *crowding out of intrinsic motivation* as the monetary incentive is thought to replace the intrinsic motivation to engage in an action (see Gneezy et al. (2011) for a summary).

For example, Gneezy and Rustichini (2000a, 2000b) find a number of crowding out results in domains outside of health. They find that paying people a small amount for each correct IQ problem solved can lead to fewer solved problems than if no monetary incentive is in place. They also find that paying money to volunteers (e.g. 1 per cent or 10 per cent of the amount of money collected while door-to-door fundraising) can decrease the amount of money volunteers collect. Finally, imposing a monetary fine for being late to pick up children from day care led parents to be late more often rather than less. Similarly, it has been shown that paying people for a short while to take a certain action and then removing

the incentive can lead individuals to provide less effort than before the incentive was introduced (Deci 1971).

In the context of medical donation, Titmuss (1971) argued that providing a monetary incentive for blood donation might decrease the amount of blood received. Mellstrom and Johannesson (2008) find some weak evidence of this crowding out in blood donation in response to an incentive worth about \$7. In their experiment, they offer the incentive to subjects to complete a health examination that was required to become a blood donor. In one treatment the incentive could only be taken in cash while in another treatment the subjects had the option to have the money donated to charity. They do not see crowding out in response to the incentive on average, but they do see it among women. Interestingly, crowding out is only present when the incentive must be taken in cash and donation rates return to the control treatment levels when the money can be donated to charity.

Reward incentives: discussion

One disadvantage of financial interventions is that pay-for-performance schemes like providing monetary incentives to engage in health behaviour are viewed by many as unfair or unethical (see, e.g. Long et al. 2008). There may be a way to mitigate this concern by making the incentives non-monetary. In the context of blood donation, individuals report a larger willingness to donate for a 10-euro voucher (to purchase books or food) rather than for 10 euros in cash (Lacetera and Macis 2010a).

As seen throughout this section, another potential disadvantage of reward incentives is that they may fail to build enduring habits. While very effective when in place, monetary incentives regularly fail to motivate continued behaviour change after they are removed. Only a few studies we’ve discussed—Charness and Gneezy (2009), Volpp et al. (2009), Giné et al. (2010), and Acland and Levy (2013)—have found evidence that paying subjects to engage in a health behaviour had a lasting impact. In addition, Acland and Levy (2013) suggest that an exogenous break in attendance (a semester break for students) eliminated this effect. One solution to this problem is to keep monetary incentives in place indefinitely, a possibility using variation in premiums allowed under the Patient Protection and Affordable Care Act (Volpp et al. 2011).

The inability for monetary incentives to lead to sustained behaviour change may be in part a function of the potential crowding out effects of such incentives, although there is still much work to be done to better understand crowding out effects and habit formation in health behaviours.

Salience and information

An assumption made by standard economic theory is that individuals have no limitation in their ability to make decisions, either in terms of the cognitive capacity to solve complex problems or the amount of time needed to do so.

To illustrate, imagine an individual who enters a shop to purchase groceries. According to standard economic theory, this individual considers all the goods he expects to be available for purchase in the shop (including all their prices or, if the prices are too costly to discover, what he expects their prices to be) and calculates which basket of goods would be best for him to buy. In doing so, the individual also considers items in others stores that

he could potentially buy instead, factoring in the time and cost it would take to drive to those shops to continue his shopping.

In reality, we have finite mental resources available to make our decisions so we are prone to ignore much of the information available and to take shortcuts in aggregating what information we do attend to. An actual individual walking into the grocery shop might forget to pick up his vitamins, be distracted by a prominent display of sweets, or simply not realize that a healthier snack alternative is available on a bottom shelf.

Another way to put this is that individuals are *boundedly rational*. Simon (1957) suggested that because individuals are limited by their cognitive capacity, as well as by information and time constraints, they lack the resources to make a truly optimal decision. Any decisions made by a boundedly rational individual are at best optimal within his or her constraints.

Bounded rationality can influence individual behaviour in several ways. For instance, individuals may exhibit forgetfulness (i.e. limited memory), may fail to pay attention (i.e. inattention), and may make decisions without collecting all the relevant information available (i.e. imperfect information). We address these three phenomena and their applications to health behaviours in turn in the following subsections.

Limited memory

No one likes to forget things. During the course of a day, however, many different pieces of information are presented to us, and we must exert mental energy to remember the important ones.

In the health realm, this limited ability to perfectly store and process information can help explain the difficulty many individuals have in adhering to a prescribed course of treatment. One potential explanation for poor medication adherence is that individuals are forgetful. Several studies have investigated interventions designed to remind people to take their medication. In theory, the ideal intervention requires no additional cognitive resources.

To this end, electronic reminders are increasingly being used to address poor medication adherence rates. These reminders alert individuals by either providing an audio or visual reminder or by sending an automatic electronic message such as a text message. Electronic reminders present two distinct advantages over other types of reminders. First, these electronic reminders *actively* remind individuals to take their medication. In contrast, passive reminders such as day-of-the-week pillboxes or blister packaging provide information that medication should be taken but are not helpful reminders if they are not seen. Active reminders are better suited for individuals whose main reason for poor adherence is forgetfulness whereas passive reminders assist individuals who need help remembering the correct dosage and combination of medication to take. Second, these reminders can be automated to arrive at a specific time. For example, if an individual is liable to forget to take his medication, a reminder provided when he is not with his pills might also be forgotten and fail to improve adherence. Third, these reminders are relatively inexpensive because they can be automated. Alternative reminders such as personal phone calls can increase adherence but often require costly time investment and commitment by healthcare providers.

Vervloet et al. (2012) review 13 randomized control trials that test the effectiveness of different electronic reminders on adherence to various types of chronic medication. They find evidence

suggesting that electronic reminders encourage medication adherence in the short run (less than 6 months) but are less effective over the long run. Furthermore, effectiveness can vary across medications for a given type of electronic reminder. While text messages are an effective tool for increasing adherence among adult patients with HIV (Hardy et al. 2011; Pop-Eleches et al. 2011) or children requiring influenza vaccinations (Stockwell et al. 2012), they have mixed effects on adherence for women taking oral contraceptives (Hou et al. 2010; Castano et al. 2012).

Forgetfulness can influence other health decisions as well. A large number of preventative care measures require individuals to remember not only to set up an appointment but also to follow through with it. The Centers for Disease Control and Prevention recommend numerous preventative screening measures such as checks for high blood pressure and diabetes screenings. Many individuals fail to take the recommended preventative care measures, even when the monetary costs of doing so are effectively zero. Forgetfulness may help to explain why individuals fail to take these recommended preventative care measures.

The difficulty in remembering to engage in recommended health behaviours has prompted both individuals and employers to seek out ways to outsource the task of remembering. The company Evive Health, LLC keeps track of when the employees of their clients are due for preventative screenings and sends personalized reminders at the appropriate times, encouraging employees to make appointments and providing information on how to do so. That employers are willing to pay companies such as Evive highlights the importance of these behavioural consequences on health outcomes.

Inattention

The salience of a given piece of information, or the degree to which that piece of information stands out relative to other information, can affect whether an individual considers it in her decision-making process. If a piece of information is not particularly salient, it might be overlooked or more easily forgotten. Consider two individuals who must remember to take their medication. The first individual has a toothache and experiences acute pain when he forgets his medication. The second individual suffers from high cholesterol and does not discern any noticeable difference in discomfort if he forgets. Because the pain of forgetting is more salient for the individual with a toothache, he may be more likely to remember his medication than the individual with high cholesterol. In this case, the salience of individual health symptoms can influence whether or not an individual remembers to take his medication.

Salience may also play a role by affecting the actual act of remembering. A person who programmes a reminder into their calendar for their next doctor's appointment is effectively making that appointment more salient. Milkman et al. (2011) report the results of a field experiment to test whether suggesting individuals write down when they intend to get an influenza vaccine (i.e. making it more salient) increases rates of vaccination. The authors study the behaviour of employees who receive a reminder mailing that provides information on the times and locations of free on-site vaccination clinics. Treated subjects were randomly assigned to receive a prompt to write down either: (1) the date the employee plans to get vaccinated or (2) both the date and the time the employee plans to get vaccinated. The authors find that the vaccination rate for

employees with the date and time prompt was significantly higher than for the control group that was not prompted to write down anything. The rate for employees with the date only prompt was directionally, but not significantly, higher than the control group. These results suggest that encouraging individuals to make a more concrete plan—making the plan more salient—can increase the likelihood of compliance.

Imperfect information

Regardless of whether a person is rational or is subject to behavioural biases, information is necessary for making optimal decisions. Consequently, decisions often change as more information becomes available. Bounded rationality can influence this process if it prevents individuals from optimally gathering or aggregating information.

In the past two decades, a growing literature has emerged looking at the effects of providing nutritional or caloric information on nutrient intake, the consumption of food, and other health outcomes. Such information could affect behaviour if individuals do not otherwise have all the information they need to make their food consumption decisions.

Several papers have studied the impact of the Nutrition Labeling and Education Act (NLEA), which mandated the nutrition labelling of all pre-packaged foods in the United States beginning in 1994. Prior to the NLEA, nutritional labelling was voluntary with the exception of products that contained added nutrients or made nutritional claims. These studies find that the enactment of the NLEA was associated with decreased body weight (for some groups) and lower probability of obesity (Variyam and Cawley 2006), increased fibre and iron intake (Variyam 2008), and lower calorie intake (Kim et al. 2000; Abaluck 2011).

Other papers in the literature have instead focused on the provision of information on the calorie content of foods. Several cities in the United States, such as New York and Philadelphia, currently require chain restaurants to post the caloric content of their menu items. These laws are in part a reaction to the concern that individuals may have imperfect information as to the true nutritional value of the items they purchase, which may in turn lead to sub-optimal food consumption. Wisdom et al. (2010) conducted a field experiment at a fast-food sandwich chain to study the effects of providing calorie information. They find that total calorie consumption significantly decreases by 60 calories on average when information on calorie content is provided. Wisdom et al. (2012) find that making healthier sandwiches a more convenient choice relative to less healthy sandwiches has significant decreases on total calorie consumption but only when the intervention is relatively heavy-handed. While these findings suggest that consumers do in fact change their consumption decisions when given more information, evidence from other studies is more mixed (Elbel et al. 2009; Bollinger et al. 2011; Finkelstein et al. 2011). In addition, many of these studies are limited by the fact that individuals who are induced to consume less due to an experimental treatment may consume more at a later meal when the experimenter can no longer observe them.

Salience and information: discussion

The extent to which we care that individuals are boundedly rational depends on whether (and by how much) individuals are made worse off because of their cognitive limitations. In the

realm of healthcare, the cognitive limitations faced by boundedly rational individuals might have important ramifications for health and their overall well-being.

Despite the research in this field, a great deal remains unknown about bounded rationality in the health domain and how to best address cognitive resource limitations. We do not yet understand in which settings the behaviours will be most affected by bounded rationality. For example, the likelihood of forgetting (and thus the effectiveness of reminders) may depend on the size of the costs to non-adherence. On one hand, the likelihood of forgetting to take a medication may be higher when a disease is serious and an individual does not want to think about it—suggesting reminders may be most valuable when the consequences of non-adherence are relatively large. Alternatively, the likelihood of forgetting might be higher when the stakes are lower—suggesting reminders will help most when the consequences of non-adherence are small.

Additionally, it is hard to trace back from a given behaviour to a particular behavioural bias or cognitive limitation, which makes it hard to identify what intervention will be most effective. For example, an individual may fail to make a mammogram appointment not because she is forgetful but instead because the costs associated with figuring out where to make an appointment are too great, or because she lacks full information on the risks of breast cancer, or because she perpetually plans to do it tomorrow. Knowing how to most successfully impact behaviour requires a better understanding of its underlying cause.

Context and framing

According to standard economic theory, rational individuals make the optimal choice given the set of options available and the constraints they face. The way in which options are presented does not influence the decision made by a rational agent. For example, a rational individual choosing between two different types of over-the-counter pain relievers is not influenced by the order in which he sees the pain relievers when walking down the pharmacy aisle. Likewise, a rational individual deciding whether to enrol in one of three healthcare plans is not influenced by the fact that his employer defaulted him into one of them.

If an individual behaves as standard economic theory predicts, her choices reflect her true preferences. But behavioural economics suggests that context and framing can play an important role in subtly influencing how we make decisions. Evidence of this influence exists across a wide range of domains, including many high-stakes environments where one might think individuals would be properly motivated to implement their optimal choices. In this section, we discuss three examples of how individuals are influenced by context and framing. First, individuals demonstrate a strong tendency to exhibit inertia around default options. Second, individuals are easily influenced by visual cues. Third, individual decisions depend on the manner in which the choice set is presented or *framed*. Understanding the contextual influences to which individuals are susceptible is critical for understanding individual behaviour and for effectively designing behavioural interventions.

Default effects

One example of the effect of context on behaviour is the strong tendency of individuals to exhibit inertia around default options.

Specifically, individuals tend to remain with their default choice even in cases where the default is randomly assigned. This *default effect* is well documented in empirical work across many different choice settings, from retirement savings decisions (Samuelson and Zeckhauser 1988; Madrian and Shea 2001; Choi et al. 2004; Carroll et al. 2009) to prescription drug home delivery enrolment (Beshears et al. 2013), to Internet privacy agreements (Bellman et al. 2001, 2004).

In a classic study on default effects outside of the health domain, Johnson et al. (1993) investigate whether individuals remain in the auto insurance plan into which they were defaulted. The authors were motivated by evidence from choices in the 1990s when the states of New Jersey and Pennsylvania introduced auto insurance plans with lower rates but limited rights to sue. Drivers in Pennsylvania were defaulted into the more expensive ‘full right’ plan whereas drivers in the neighbouring state of New Jersey were defaulted into the less expensive ‘limited right’ plan. Because the underlying choices—the full right plan on one hand and the limited right plan on the other—were the same across states, whether drivers were defaulted into one plan or the other was not expected to impact behaviour. However, a reported 75 per cent of Pennsylvania drivers stayed with their ‘full right’ plan whereas only 20 per cent of New Jersey drivers switched to the ‘full right’ plan.

Defaults play an important role in many health domains, including insurance plan choice. For example, people who remain eligible for Medicare Part D are defaulted into their prescriptive drug coverage plan from the previous year. Ericson (forthcoming) shows that few enrollees switch from their plan from the previous year, even when relative prices of plans change. Likewise, Handel (2013) looks at the behaviour of enrollees in a Preferred Provider Organization (PPO) health insurance plan after relative prices of plans changed significantly. As a result of the price changes, the current plan of some enrollees became strictly dominated by an alternative PPO health insurance plan (that is, for any possible level and type of medical expenditure, their current plan would require higher combined premium and out-of-pocket costs than the alternative PPO plan). Despite these enrollees’ plans being strictly dominated, Handel finds that 89 per cent of the enrollees choose the default: to remain in their current plan. Default effects can similarly be found in employee contributions to health-care flexible spending accounts (Schweitzer et al. 1996).

Default rules often affect whether individuals participate in certain programmes. Default rules generally either require explicit consent (e.g. an opt-in rule) or presume consent (e.g. an opt-out rule). In the United States, deceased organ donation follows an opt-in rule, requiring explicit consent from the deceased (e.g. having previously joined a state registry) or consent from the deceased’s next-of-kin. But not all countries follow an opt-in rule. A number of European countries follow an opt-out rule where individuals are automatically assumed to be a donor unless they previously chose to remove themselves from the registry. So long as the costs to opting in or opting out are small, the default rule should have little influence on donor registration rates. Johnson and Goldstein (2003, 2004) show, however, that there is considerable variation in organ donor registration rates by the default rule. They report that at the time of their research the effective consent rate was around 17 per cent in the United Kingdom, which followed an opt-in rule, and was 98 per cent in Belgium, which

followed an opt-out rule. Of the countries surveyed by the authors, the difference in participation rate between the highest opt-in and lowest opt-out countries was nearly 60 percentage points.

In a corresponding hypothetical choice experiment about organ donation, Johnson and Goldstein randomly assigned individuals to one of three default conditions: (1) opt-in, (2) opt-out, and (3) neutral. Under the third condition, individuals were not defaulted into or out of the donor pool but were instead asked to make an ‘active choice’ between either donating or not donating. They find that the average participation rate by individuals under the opt-out condition is significantly higher than that of individuals under the opt-in condition. Johnson and Goldstein also find that the neutral condition is not significantly different from the opt-out condition, suggesting that asking individuals to make an active choice might be more effective at generating organ donor registrations than the opt-in policy. Similar arguments about organ donation are made in the popular press (Thaler 2009). The United Kingdom and a number of US states (including, notably: Illinois, California, and New York) have changed the request for organ donor registration from opt-in to active choice.

However, it is too soon to tell whether these changes will increase organ donor registration rates. Experimental evidence on real organ donor registrations finds that the active choice frame does not improve registration rates over an opt-in frame, and may lead to lower consent rates from next-of-kin (Kessler and Roth 2014b).

There are a number of explanations for why individuals tend to exhibit inertia around default options. Traditional economic theory suggests that the default effect could be accounted for by the presence of switching or transaction costs. These costs do not have to be monetary in nature but can also include time and effort that individuals have to expend to switch away from the default. If the costs to switching are large enough, individuals will actually prefer not to switch from their default option. Inertia around default options could also be rational behaviour if individuals believe the default option is an implicit recommendation by the person who chose the default. For example, an individual may view a default health plan choice as an implicit recommendation from her employer.

Default effects are often present even when the apparent costs to switching are negligible and the likelihood of the default being viewed as an implicit recommendation is small. An alternative behavioural explanation for such an effect is the bounded rationality of individuals. For example, an individual may be enrolled in the same prescription drug plan as the previous year (the default option) because after the initial enrolment period, he paid little attention to any changes in circumstances that might induce him to switch. Because of this inattention, the individual fails to make a conscious choice and so is automatically enrolled into his plan from the previous year.

Alternatively, people may simply exhibit *status quo bias*, a preference for the current status quo independent of whatever the best option is, or *omission bias*, a preference for inaction over action. Any combination of these explanations could lead to inaction and thus the observed default effect. Regardless of what the true underlying mechanism is, however, it remains that defaults can have a significant influence on individual choices.

Visual cues

Visual cues and other environmental factors can also play a role in individual decision-making. Benartzi and Thaler (2007)

find that the number of lines displayed on an investment elections form influenced the number of funds into which individuals invested their retirement savings. Individuals were randomly given either a form with eight lines or a form with only four lines (but a nearly costless way to increase the number of lines). Of the individuals given the four-line form, only 10 per cent invested in more than four funds. By comparison, approximately 40 per cent of individuals given the eight-line form invested in more than four funds.

Within the realm of health, there is an extensive literature looking at how visual cues can affect food consumption and food choices. Everything from the visibility or salience of food to the size and shape of food packaging can influence individual consumption. For example, people consume more food when they are given larger serving bowls (Wansink and Cheney 2005) or there is greater perceived variety (Rolls et al. 1981; Kahn and Wansink 2004). They pour 30 per cent more alcohol when using short, wide glasses rather than tall, narrow glasses (Wansink and van Ittersum 2007).

The environment in which we eat can also affect food consumption choices. An individual purchasing groceries may be more likely to buy tempting goods, such as chocolate bars, if they are located near the register where the effort cost of adding them to the purchase is low than if they are located at the opposite end of the shop. In this example, the convenience of the chocolate bars may influence the likelihood of purchase. Hanks et al. (2012) studied whether the conversion of a cafeteria lunch line into a 'convenience line' that only offered healthy food options influenced the consumption of healthy (versus unhealthy) foods. The authors find that following the introduction of a convenience line, the consumption (measured in grams) of healthy foods chosen did not change but the consumption of unhealthy foods decreased significantly by 27.9 per cent. The share of total consumption from healthy foods increased on average while the share from unhealthy foods decreased.

Framing

Another assumption about rational economic actors is that their preferences are consistent. This consistency implies that the way a set of choices is framed or presented does not influence the individual's decision so long as no additional information is conveyed by the frame.

In a famous example, Tversky and Kahneman (1981) demonstrated that framing affects choices using a hypothetical life-or-death scenario. Their study asked participants to consider a scenario where the United States is preparing for the outbreak of a disease, which is expected to kill 600 people. There are two proposed programmes to combat the disease. The first set of respondents to the survey were told:

- ◆ If Programme A is adopted, 200 people will be saved.
- ◆ If Programme B is adopted, there is 1/3 probability that 600 people will be saved, and 2/3 probability that no people will be saved.

The second set of respondents were instead told:

- ◆ If Programme C is adopted, 400 people will die.
- ◆ If Programme D is adopted, there is 1/3 probability that nobody will die, and 2/3 probability that 600 people will die.

Both groups were then asked which of the two programmes they would favour. The first programme for each group involves no risk (the outcome is presented with certainty) whereas the second programme involves some risk-taking. Of the respondents in the first group, 72 per cent chose Programme A over Programme B. Of the respondents in the second group, 78 per cent chose Programme D over Programme C. The authors point out, however, that Programme A and Programme C are equivalent, as are Programme B and Programme D.

When the estimates of the consequences of each of the programmes were framed in terms of lives saved, respondents preferred the programme that offered the certain outcome. Yet when the consequences were instead framed in terms of lives lost, respondents preferred the programme that involved risk-taking. As it turns out, in situations involving risk, individuals often exhibit such preference reversals depending on whether the outcome is framed in terms of gains or losses. Individuals are generally risk averse when facing gains and risk seeking when facing losses (Kahneman and Tversky 1979).

While the proposed scenario of a disease outbreak was hypothetical, such framing effects have been shown to have consequences for individuals making real decisions regarding their health. McNeil et al. (1982) find that individuals are more likely to prefer surgery to radiation therapy (which has no risk of death during treatment) when told that surgeries face a 90 per cent survival rate as opposed to a 10 per cent mortality rate. In another study, women's attitudes towards potential side effects of tamoxifen, a medication taken by high-risk women to help prevent the first-time development of breast cancer, varied depending on whether they were informed that 2.8 out of 100 women experience cardiovascular problems as a side effect versus 28 out of 1000 women (Zikmund-Fisher et al. 2008). While the information presented is the same in either case, participants were more concerned about the potential side effects when randomly informed of the risk statistic using the larger denominator. The way in which this information is framed can significantly affect the decision-making process.

Context and framing: discussion

Recognizing the influence that context and framing can have on individual behaviour is important, especially when the choices lead to significantly different outcomes—some of which might make individuals better off. It is often difficult to separately identify the effects of context and framing from other factors that may come into play, and so any estimates of the effects of these cues on behaviour and welfare must be considered carefully. Even with this caveat, however, it is clear that context and framing can significantly influence individual choices and outcomes. For example, Handel (2013) finds that, on average, individuals who are defaulted into their health plan choice from the previous year (but are given an option to switch) forgo roughly \$2000 in implied savings by staying in their default plan rather than choosing an alternative option. If individuals choose to stay in the same plan because they were defaulted into it, rather than due to switching costs, the decision can represent a substantial loss to individuals. Furthermore, if defaults lead to low levels of switching, the factors that influence individuals in their initial decision can end up having long-term effects.

One way to reduce the influence of default effects, visual cues, and framing is to help individuals overcome these biases while

making their decisions. For example, providing information that lessens the complexity of a decision can decrease default effects. Enrolees in prescription drug plans who are provided with information regarding the relative costs of each of the available plans are much more likely to switch from their current plan (the default) than those who do not receive such information (Kling et al. 2012).

Similarly, rather than requiring individuals to either opt in or opt out of participation or enrolment in a programme, an alternative solution is to require that these individuals actively consider the decision being made. This can be achieved either by designing the choice environment so that individuals are forced to consider whether they really want to opt in (or out) or by requiring that they make an active choice.

It is sometimes difficult or impossible, however, to design an environment that does not influence behaviours in some way. And in many scenarios involving public health, it may actually be preferable to use behavioural economics to design choice environments so as to encourage certain behaviours. For example, it is extremely difficult to design a cafeteria environment that does not influence food consumption decisions. Food items must be placed in some order and in some location, and so influencing food consumption is unavoidable. Often the current design of an environment is simply one potential design option (just the one into which the policymaker has been defaulted).

Box 6.7.2 discusses approaches to regulatory policy based on the insights of behavioural economics.

Although contextual influence has long been recognized, Thaler and Sunstein (2008) popularized the topic with their discussion of *choice architecture*—the design of the environments in which individuals make choices. As they note, behavioural economics can be a useful tool in nudging individuals towards behaviours that are beneficial while still allowing individuals complete autonomy

in making their choice. A choice architect may choose to use an opt-out rule when there is underutilization of something seen as beneficial. For example, influenza vaccinations are often encouraged in part because individuals who do not receive the vaccination impose a negative externality on other individuals. In such instances, designing a behavioural intervention where individuals must opt-out of receiving a vaccination can increase overall vaccination rates (Chapman et al. 2010; Keller et al. 2011). Similarly, a school may design the food display in their cafeteria so that salad options are placed before dessert options, and an employer may encourage savings by requiring individuals to opt out of contributing to a savings plan.

Social forces

Humans are social animals who mirror the actions of others, behave differently when they know that others will learn about their actions, and respond to requests. These features of human behaviour suggest three predictions. First, individuals informed about the actions of others will tend to conform to others' behaviour. Second, individuals who become aware that they are being observed will take actions that make them appear more favourably in the eyes of others (e.g. they will take actions that make them look more generous or more responsible). Third, individuals will be more likely to take an action when asked to do so by someone else. These social forces—which can be partially justified by the rational model and which we think of partially as behavioural—influence a wide variety of behaviours, including a number in the health domain. For each of the following three subsections, we provide evidence from health and non-health settings. As will be discussed at the end of this section, we believe social forces to be an area of behavioural health economics that has the opportunity to grow in the coming years.

Responding to the actions of others

It has been well documented that individuals informed about the actions of others tend to conform to others' behaviour. One way in which researchers have established this fact is to provide experimental subjects with *social information*: specific information about the actions of other people. Individuals who are provided with such information respond by taking actions that are more similar to the behaviour of others.

Outside of the health domain, this effect of social information has been observed in settings including charitable giving, environmental protection, and job choice. Individuals are more likely to donate to charity when they are told that others also donate. Frey and Meier (2004) find that students are more likely to make charitable donations to student funds at the University of Zurich when they are told that 64 per cent of students donate to the funds (64 per cent was a recent semester's average) rather than being told that 46 per cent of students donate to the funds (where 46 per cent was a 10-year average). Individuals also donate more money to a charity when they are told that others donated larger amounts. Shang and Croson (2009) find that the amount of money donated to a public radio campaign increases when donors who have called in to make a gift are told of a large recent donation of \$300 rather than being told of a smaller donation of \$75 or being told no information about a previous donation. This effect on donation amount works even more strongly in the negative direction;

Box 6.7.2 Behavioural economics and lessons for regulatory policy

Cass R. Sunstein, co-author of *Nudge* (2008) and Administrator of the White House Office of Information Regulatory Affairs (2009–2012), suggests four promising approaches to regulatory policy based on the insights of behavioural economics:

1. 'Using disclosure as a regulatory tool, especially if disclosure policies are designed with an appreciation of how people process information.
2. Simplifying and easing choices through appropriate default rules, reduction of complexity and paperwork requirements and related strategies.
3. Increasing the salience of certain factors or variables.
4. Promoting social norms through private–public partnerships and other approaches that operate in the service of agreed-upon public goals.'

These approaches address some of the commonly cited behavioural biases studied in behavioural economics and mentioned in this chapter.

Text extracts reproduced from Sunstein CR, Behavioral economics and regulation in Zamir E, Teichman D (eds), *Oxford Handbook of Behavioral Economics and the Law*, Oxford University Press, New York, USA, Forthcoming, by permission of Oxford University Press Inc.

people donated significantly less when the donation amount cited is below what they gave in the previous year (Croson and Shang 2008). Individuals are also more likely to engage in environmental protection when they are told that others engage in environmental protection. In a study on towel reuse, Goldstein et al. (2008) find that hotel guests are significantly more likely to reuse their towel—saving the water and electricity required to wash it—when they are told that 75 per cent of hotel guests reuse their towels rather than being given a generic environmental appeal. As with the charity examples, information can also impact the extent to which an individual engages in environmental protection. In a related setting, Allcott (2011) finds that sending households report cards comparing their electricity use to the electricity use of similarly sized households can decrease electricity usage by as much as an 11–20 per cent short-run price increase. On job choice, Coffman et al. (2014) find that individuals are more likely to accept a job as a school teacher when they are told that 84 per cent of accepted applicants took the job in the previous year.

That individuals respond to the actions of others has been shown to be important in the health domain as well. Here we focus on binge drinking and smoking, contexts in which individuals have been shown to conform to the behaviours of those around them.

Most students across the country have beliefs about the drinking habits of other students that are ‘too high’—they think their peers drink more heavily than their peers actually do. Researchers have shown that beliefs about peer alcohol consumption correlate with own alcohol consumption. Perkins et al. (2005) perform a multivariate analysis of survey data from 130 schools and find overestimates of alcohol consumption among peers and a strong statistical relationship between those beliefs and own alcohol consumption, controlling for all available demographic variables. A similar approach has found a correlation between the smoking behaviour of adolescents and their perceptions of other teens smoking (Eisenberg and Forster 2003).

This correlational evidence is suggestive of a causal link in which individuals respond directly to their beliefs about others’ drinking or smoking habits when making their own decision of whether to drink or smoke. This correlational evidence, however, is far from conclusive. It is quite possible that the causal link goes in the opposite direction. For example, teens may drink or smoke in groups; those who smoke may be more likely to observe others drinking and smoking and thus generate estimates about the prevalence of those behaviours among the rest of their peers that are too high. Similarly reported beliefs about others’ drinking may be influenced by own drinking and the assumption that others are similar to oneself, leading those who drink or smoke more to believe that others drink or smoke more as well.

A true experiment that manipulates the information provided to individuals could more successfully show a causal link. For the case of alcohol consumption, DeJong et al. (2006) provide this experimental demonstration in a study involving 18 institutions of higher learning across which they randomized whether the schools ran a 3-year social norms marketing campaign (SNMC). These SNMCs educated college students about the actual alcohol consumption of students at the school. Many colleges and universities had previously implemented these types of SNMCs to inform students of the actual drinking behaviours of their students and so one aim of the research was to experimentally test their effectiveness.

The authors gathered self-reported beliefs about the alcohol consumption of other students and the self-reported own consumption from the Survey of College Alcohol Norms and Behaviour conducted before and after the 3-year SNMCs. Students surveyed at schools that were randomly selected to have a campaign reported larger decreases in drinking from pre survey to post survey on a number of dimensions (including a composite drinking scale, recent maximum consumption, and drinks consumed when partying). This decrease was associated with a decrease in reported beliefs about the drinking of others at the school. The authors also note that the decrease in drinking was more pronounced at schools with more intensive SNMCs.

When others are watching

Both inside and outside the health domain, individuals take actions that make them look more generous and more responsible when they believe that they are being observed. These effects are stronger when individuals care more about the person or persons observing them.

Outside of the health domain, being observed affects voting, charitable giving, and providing other public goods (i.e. taking costly actions that benefit others). On voting, Gerber et al. (2008) show that informing individuals that whether or not they vote is public record (and that their voting is being watched by researchers) increases the likelihood of voting over a standard message. Voting rates are even higher when individuals are told that their voting records will be sent to their neighbours after the upcoming election. In charitable giving, individuals care about what others learn about their donations. Harbaugh (1998) demonstrates that when a prestigious law school switches reporting all donations to reporting donations by category, donations become significantly more clustered at the lowest amount that achieves a certain level of recognition (e.g. many more donations at \$500 when the reported category is \$500–999). Similarly, Kessler et al. (2014) show that alumni of a large university are more likely to donate in consecutive years when they know they will receive public recognition for doing so.

In the health domain, image concerns affect individuals’ willingness to engage in charitable health donation behaviours, including donating blood. Lacetera and Macis (2010b) looked at donation records from an Italian town; they found an increase in likelihood of blood donation as individuals approach the threshold for a symbolic prize (a medal) for their donations, but only if the winners of the medals are announced in the local newspaper and awarded publicly.

Combining social forces with monetary incentives can potentially strength the effect of an intervention. Haisley et al. (2012) increase the percentage of employees who complete a health risk assessment by combining a regret lottery (described earlier in ‘Designing incentives using behavioural economics’) with a social component where individuals could earn more if other employees—whose identities they knew—also completed the assessment. This treatment worked better than a standard reward incentive of a similar expected value.

Requests from others

Individuals are more likely to take an action when asked by some one else to do so. Encouragement or discouragement from others (also known as *peer pressure*) is a powerful social force that can influence individual behaviour inside and outside of health contexts.

Outside of the health domain, Meer and Rosen (2011) show that being more likely to be called on the phone in a university fundraising campaign makes donors much more likely to make a donation. Similarly, DellaVigna et al. (2012) show that individuals are less likely to answer to the door and less likely to make a donation in a door-to-door fundraising campaign when they are warned that an individual is coming to make a request. They interpret this result as individuals being worried about facing peer pressure and choosing to opt out when they know they will be asked to donate. Freeman (1997) reports that people are much more likely to volunteer when asked by a friend.

A number of health interventions attempt to leverage individuals' favourable responses to requests from others. Campbell et al. (2008) report on the results of a randomized controlled trial on teen smoking using 59 schools and 10,730 students aged 12–13 in Wales. Control schools received the standard smoking education. Treated schools had a special programme that included peer mentors: students who were trained to have informal conversations with their peers in which they discouraged smoking. Treated schools showed a decrease in the likelihood that students smoked 1 year later. By the second year after the intervention, the effect is attenuated (and no longer statistically significant), although students at the treated schools are still directionally less likely to smoke.

Kelly et al. (1991) report that training individuals identified as opinion leaders in their communities to endorse safe sex among gay men at risk of HIV drastically decreased the extent to which gay men engaged in unprotected anal intercourse (as measured by surveys before and after the intervention). Control cities that did not have individuals trained to endorse behaviour change did not show a decrease in unsafe sex during the same time period.

Long et al. (2012) investigate a peer mentoring treatment on glucose control for individuals with diabetes. In one treatment, subjects with poor diabetes control are paired with mentors who previously had poor control but have since improved. On average the mentor–mentee pairs talk once a week at the start of the study and once every 2 weeks at the end of the study 6 months later. The peer mentor group shows a large and significant improvement in glucose control. The authors found that this group also outperformed a financial incentive treatment where individuals were paid \$100 or \$200 for decreasing their glucose level. Similarly, the Geisinger Health System has been able to achieve better patient outcomes by having nurses follow-up with patients to monitor medication use and address possible questions and concerns (Cutler and Everett 2010).

Social forces: discussion

Social forces have been shown to have a powerful effect on behaviour in a number of domains outside of health, including charitable giving, environmental protection, voting, and job choice. The growing evidence on how social forces impact behaviour in health domains suggests that these forces may be particularly effective in affecting health behaviours as well.

If shown to be effective, social forces have a number of particular benefits in the health domain. First, leveraging social forces can be significantly less expensive than monetary incentives and thus may provide a very cost-effective way to affect behaviour (Hollingworth et al. 2012). Second, while we have yet to see many studies with long follow-up periods to test for the effectiveness

of social treatments in the long term, there is reason to believe that social forces might build sustaining habits for healthy behaviour. Unlike a monetary incentive, which is either on or off, social incentives might have lingering effects. Once someone has been told that fewer people drink than he suspected, he may hold on to that information and it may still affect him months or years later. A peer mentor might continue to provide mentorship even after a study intervention period is over. In this way, social forces have the potential to provide longer-lasting effects. Additional research is needed to investigate the sustainability of these forces—research that we hope to see conducted in the coming years.

Conclusion

This chapter outlines findings from behavioural economics, highlighting four topic areas: reward incentives, salience and information, context and framing, and social forces. Results from each of these topic areas suggest interventions that can affect health behaviours.

As emphasized in the introduction, policymakers must be responsible with when and how they use available interventions to affect health behaviours. Policymakers must look for constraints, externalities, or behavioural biases to justify intervention. Fortunately, some individuals with behavioural biases may explicitly ask for interventions. They may recognize that they need help to engage in certain desirable behaviours like going to the gym, eating healthily, or taking their medications. In these cases, individuals will happily sign up for studies designed to test ways to impact behaviour, allowing us to conduct more research. In addition, they will happily opt in to programmes policymakers design to effectively encourage behaviour change.

Previous research has provided us with some insights into how to motivate behaviour, but exciting work remains to be done. One open question of particular importance—the proverbial Holy Grail of behavioural economics research in health behaviour—is how to create habit formation among individuals who want to engage in healthy behaviours and have trouble doing so. In this chapter, we saw examples in which a treatment that was in place for a while and then removed might have created a habit for visiting the gym, at least for a short while (Charness and Gneezy 2009; Acland and Levy 2013). In addition, we saw success in breaking the hold of an addictive behaviour like smoking (Volpp et al. 2009; Giné et al. 2010). But there are many more examples of interventions failing to help subjects form healthy habits that persist after the intervention is removed. By better understanding habit formation we can develop interventions that can be cost effective and have significant policy appeal.

Governance and management of public health programmes

Eng-kiong Yeoh

Introduction to governance and management of public health programmes

In the 2007 publication of the World Health Organization (WHO), *Everybody's Business: Strengthening Health Systems to Improve Health Outcomes*, a critical question asked is 'Why aren't health systems working better?' (WHO 2007). The publication begins with the observation: 'The world has never possessed such a sophisticated arsenal of interventions and technologies for curing disease and prolonging life. Yet the gaps in health outcomes continue to widen. The power of existing interventions is not matched by the power of health systems to deliver them to those in greatest need in a comprehensive way, and on an adequate scale' (p. iii). The WHO proposes a framework for action to strengthen health systems. In the health systems framework, governance and leadership, also referred to as stewardship, is the critical function. Governance refers to 'the wide range of functions carried out by governments as they seek to achieve national health policy objectives', and involves overseeing and guiding the whole health system (WHO 2007). It is pivotal in ensuring that the different components of the system function effectively together to achieve objectives and goals. Good governance and effective management is critical to the performance of health systems (Lauer 2001; WHO 2002, 2007; Mills et al. 2006; Institute on Governance 2011). *Governance Matters*, a global study on governance by the World Bank, found empirical evidence of a strong causal relationship between better governance and better developmental outcomes (Kaufmann et al. 1999). The study was based on a new database of over 300 governance indicators compiled from different sources in over 150 countries. The elements of governance examined were: how governments were selected, ability to formulate and implement sound policies, and the institutions which govern interactions with the state. There was a strong causal relationship of good governance and higher per capita incomes, lower infant mortality, and higher literacy. In a subsequent study of health system efficiency, the WHO also found a positive correlation between both the health and overall efficiency measures and 'index of government effectiveness' (Lauer 2001; Mills et al. 2006). There have been an increasing number of studies that have found that effective or good governance is a

critical factor for achieving the goals and objectives of an organization (Institute on Governance 2011).

In the current world order, governance of public health programmes can no longer be considered in isolation from the wider system of public health governance, impervious to influences in the wider context (WHO 2007). Public health programmes vary enormously in size, scope, and coverage, and may originate locally from community groups and organizations or be commissioned by provincial or national governments and non-government organizations (NGOs) and foundations. The programmes may also be part of a growing number of huge global health initiatives (GHIs) that is changing the whole global health governance landscape. Globally, development assistance for health grew from US\$5.6 billion in 1990 to US\$21.8 billion in 2007 (Ravishankar et al. 2009). In 2012, 10 years after it was set up, The Global Fund to Fight AIDS, Tuberculosis and Malaria (GFATM) channelled US\$3 billion annually (GFATM 2013). These global public health programmes are multinational and disbursements of funds are channelled increasingly through NGOs and in direct bilateral assistance to governments rather than the traditional intergovernmental agencies such as the agencies of the United Nations (UN), the UN Population Fund (UNFPA), the UN Children's Fund (UNICEF), and the WHO (Ravishankar et al. 2009). Issues have arisen and concerns been expressed that national health priorities may be distorted by global health priorities. National health systems with limited capacity in their infrastructure find it difficult to cope with the competing priorities of different donors with varying requirements for governance structures and mechanisms and reporting. Governance and management of public health programmes must be understood and studied in the wider context of public health management and governance.

Evolution of the concept of governance

The concept of governance and its applications have evolved, since the origins of the word derived from the fourteenth-century Latin *gubernantia* which meant 'to steer'. In subsequent usage it became equated with the exercise of authority and a system of government. The *Oxford English Dictionary* describes governance as

‘the act or manner of governing, of extending control or authority over the actions of subjects; a system of regulations’. In recent usage, the concept of governance is no longer understood to be synonymous with government (Rosenau 1995; UNDP 1997). Government-the-state is conceived as one form of governance, which is highly formalized (Dodgson et al. 2002). Governance transcends the state, and incorporates the private sector and civil society (Rosenau 1995; UNDP 1997). This is a reflection of the changes in the relationship between the ‘governing’ and the ‘governed’ in current society where the ‘governing’ need to seek the consent of the ‘governed’ to secure its legitimacy. It also reflects the prominent roles and the increasing influence of two other institutions of society—the for-profit private sector and civil society—in all aspects of social pursuits. The Institute on Governance observed that the concept of ‘governance’ had evolved in its application to be used as a fundamental consideration in most disciplines in the last two decades (Institute on Governance 2011). Governance has been conceptualized from different perspectives in a broad range of disciplines—political, social, policy and health sciences, law, and international relations and has been applied to diverse aspects of social endeavour and scholarly inquiry. This has led to a proliferation of definitions consistent with their respective conceptualization and application. Two definitions of governance are of particular relevance to, and reflect the essence of, public health. The first, the United Nations Development Programme (UNDP), defines governance as ‘the exercise of political, economic administrative authority of a country’s affairs at all levels’. Governance comprises the complex mechanisms, processes, and institutions through which citizens and groups articulate their interests, mediate their differences, and exercise their legal rights (UNDP 1997). The UNDP definition recognizes the political and economic nature of social life, and the roles and interdependencies of the pillars of organized society such as the state, private sector, and civil society. The UNDP conception of governance incorporates the basic premise of democratic societies of the relationship between state and citizens. A common theme of the different conceptions of democracy is the exercise of collective self-determination of communities based on the consent of the governed (Scholte 2005). Governance in democratic societies emphasizes the source legitimacy, limits of authority, the purpose for which authority given should be applied for, and accountability in its exercise. A second, even broader, definition of governance in a conceptual review of global health governance is ‘the action and means adopted by a society to promote collective action and deliver collective solutions in the pursuit of common goals’ (Dodgson et al. 2002). This recognizes the whole range of cooperative endeavours undertaken in society, from informal arrangements and agreements by groups of individuals in the community to the highly formalized form of established rules, conduct, and procedures institutionalized in government. There are virtually infinite mechanisms, many of which fall outside the realms of government, all contributing in important ways to the collective actions of society in the pursuit of common goals. These two conceptions of governance are of particular relevance to public health, which as defined by Acheson, and adopted in this publication is ‘the science and art of preventing disease, prolonging life, and promoting health through the organized efforts of society’ (Acheson 1988, p. 1). A mono focus on the role of the state in health governance neglects the equally important roles and influence of civil society and the private

sector in contributing to efforts to promote and improve health. It has been argued that an exclusive focus on the state in governance, undermines our ability to govern effectively (Ollila 2005; Kempa et al. n.d.; Renukumar n.d.).

Public health governance: conception

The broader conceptions of governance will underpin the approach used in this paper as they enable a holistic perspective and better understanding of the mechanisms in government, the private sector, and civil society, their interactions and interdependencies, their complex and dynamic nature, and how they influence and enable the goal of improving the health of people. This is reflected in the two following definitions: ‘Health governance concerns the actions and means adopted by a society to organize itself in the promotion and protection of the health of its population’ (Dodgson et al. 2002, p. 6); ‘Public health governance is the means by which society collectively seeks to assure the conditions under which the population can live with the highest possible level of health and well being’ (Bennett et al. 2009, p. 207). Public health concerns health of populations in societies; public health governance is health governance and the two terms will be used interchangeably in this chapter. Health governance is multilayered with mechanisms at: (1) supranational, that is, global, regional, and international; and (2) national, that is, federal, provincial, and local levels, with close and complex interactions between the different levels. Public health programmes may be initiated at every one of these levels and are not only closely interrelated but also integrated in many facets. Supranational global initiatives inter-digitate with local programmes, and regional with provincial. The proliferation of GHIs initiated by private donors, foundations, and donor countries for different diseases and health problems influence priority setting of national health programmes. In addition, the multiplicity of competing demands of the different donors can create pressures for local health systems with limited planning and delivery capacity. A discussion of governance of public health has to examine the structures and mechanisms at each of the levels, their interactions, and interdependencies.

Public health governance: a systems framework

Governance has been applied to specific and a relatively narrow scope of collective actions such as in clinical and corporate governance, and to the broader concept of global health governance (Dodgson et al. 2002). A systems framework and typology is useful in understanding this complex and developing field of inquiry. Systems theory has enabled the development of a new conceptual underpinning for studying and understanding social systems which are inherently complex. Systems theory has been applied in the WHO’s framework to strengthen health systems which comprises six components, referred to as ‘building blocks’ (Fig. 6.8.1). The six system building blocks which are core functions of every health system are: (1) service delivery; (2) health workforce; (3) information; (4) medical products, vaccines, and technologies; (5) financing; and (6) leadership and governance (WHO 2007). These six building blocks are interdependent and interrelated components of the health system, and need to be coordinated to

Fig. 6.8.1 The WHO health system framework.

function together as a whole. Strengthening health systems, that is, making them more effective, involves improving these components and managing their interactions. Systems theory provides the conceptual basis for studying, understanding, and researching how these six building blocks interrelate, and how their interdependencies can be better managed to strengthen health systems to improve health outcomes. The systems approach will also enable the definition of the desirable attributes of health systems needed for effectiveness.

Systems theory has also been applied in understanding global health governance as a complex adaptive system (Hill 2011). Complexity theory provides a frame for understanding of, and providing insights into, the complex and constantly evolving polyvalent relationships of the diverse actors, and the reconfigurations of influence in the multitude of networks, in global health governance. The key concepts of general systems theory can be applied to health governance as a system, and comprise the following (Kast and Rosenzweig 1972):

1. A system is composed of interrelated parts which are interconnected.
2. A system is not the sum of the components, and can only be explained in totality.
3. Systems may be open or closed, social systems are inherently open.
4. Systems have boundaries which distinguish them from their environments; however, boundaries are very difficult to define in social systems.
5. There is a hierarchical relationship between the components of a system, with subsystems, and both are part of a suprasystem.
6. Open systems are in a dynamic relationship with their environment, receiving inputs which are transformed into outputs which are exported.

7. Systems are subject to the forces of entropy; in open systems, however, the process can be arrested or may be reverted to a state of negative entropy by virtue of its ability to import resources from its environment and transform them into outputs.
8. Information relating to the outputs of a system, feedback into the system, and facilitating changes in the transformation process.
9. Open systems tend to become more differentiated, organized, and elaborated.
10. Social systems comprise individuals and subunits, with different values and objectives and seek multiple goals.
11. Equifinality is a characteristic of open systems, which achieve their respective objectives with diverse inputs and different processes.

A public health governance system is part of the wider governance system of human societies (the suprasystem), wherein lie the mechanisms and actions which define the social determinants of health. The components (the subsystems) of health governance are the entities of the state or government, the private for-profit sector, and civil society, and their respective institutions, structures, and mechanisms (subunits). The health governance functions of these three entities interact and are interrelated and are in a dynamic relationship with the environment of the wider governance system in society. A framework for public health governance provides a theoretical basis for studying and understanding the complex mechanisms and processes of health governance within the three component entities, and the interactions and interrelations between them. It also provides a conceptual basis for appreciating and studying the evolutionary changes in health governance which are observed over time resulting from the interactions and feedback to the system. The prominence of civil society, the powerful influence of the private sector, and the redefined role of the state in governance can be better appreciated with this frame. Table 6.8.1 shows the framework and typology which will be used in this chapter.

Public health governance can be conceived as a complex system of the interactions and interdependencies of the institutions of current society—the entities of the state, private sector, and civil society—in collectively seeking to assure the conditions under which populations can live with the highest possible level of health and well-being. These three entities can be conceived as horizontal

Table 6.8.1 Public health governance—a systems framework

Levels	Entities/components	Structure
Supranational:	Government/state	Institutions
Global	Private [for-profit] sector	Organization
Regional	Civil society	Instruments/tools
International	Hybrids of government:	Mechanisms/processes
National:	Private	
Federal	Civil society	
Provincial

components or subsystems each with distinct structures, institutions, organization, instruments and tools of influences, mechanisms, and processes for interactions within and between the component entities. The interactions and interdependencies of these three horizontal entities, inter-digitate in a second, hierarchical dimension at either the national or supranational levels. The organizational context of governance within the three component entities and at the two hierarchical levels is a third dimension of the system. These distinctions provide the basis of defining the distinct characteristics of each of these component subsystems (Fig. 6.8.2).

The private sector

The private sector refers to all the private business organizations and enterprises, including the informal market sector, with a profit objective. The private sector creates jobs and generates income, and influences socioeconomic policies and politics, to create an environment which is conducive for markets and enterprise (UNDP 1997). The organization of the sector varies considerably, comprising a diversity of arrangements from the family-based informal sector to highly organized, vertically integrated and horizontally diversified corporations, at national, multinational, and transnational levels. Different organization forms have also emerged, reflecting the dynamic environment of the complex nature of social systems, and include: strategic alliances, partnerships, and collaborative networks, both within the private sector and with civil society and government.

The governance instruments available to the private sector are wide-ranging, and include a number of those available to government: exhortation, expenditure, direct provision and regulations. The significant difference is, in traditional application of these instruments by the private sector, it is without the authority of the state, and in particular the coercive power of the state to impose penalties, withhold benefits, and restrict individual decisions.

However, even this has changed, with the evolving role of government and hybrid forms of public–private governance, the private sector may be given authority normally bestowed to the state, either through the contracts to the private sector in ensuring compliance with state regulatory functions or outright delegation which may be explicit and embodied in the law (Freeman 2000; Kempa et al. n.d.). One example is the passage of legislation in the US Congress requiring hospitals to be accredited by the Joint Commission on Health Care and Accreditation of Health Organizations (JCAHO) as a condition for participation in the federal social insurance programme, Medicare. Another prevalent practice is the delegation of health professional regulations to health professions. These hybrid roles have been referred to as ‘the privatization of governance’ (Scholte 2005). Corporations have been described as the most influential and powerful organizations in contemporary governance. They have available substantial controlling resources, ability to frame and influence discourses, flexibility in pursuing their objectives and enterprise in finding niches (Freeman 2000; Kempa et al. n.d.). ‘Private government’ has been used to describe the powerful influence of the private sector in ‘governing states’ through the threat of flight of capital as a means of getting governments to enact socioeconomic policies which are conducive to corporate profit maximizing, and in governance of security in non-state spaces, which are privately owned but open to public access, to varying degrees, such as shopping complexes, parks, and golf courses, where the police of the state are mobilized to do the ‘bidding’ of private security (Kempa et al. n.d.). The private sector’s role in health governance is pervasive, as providers, financiers, marketers, commissioners, and employers.

The proliferation of GHIs initiated by private donors, foundations, and donor countries have a strong influence on priorities of national health programmes and can create significant pressures for local health systems.

Civil society

Civil society comprises individuals, and formally organized or informal groups of individuals, interacting socially, economically, and politically. Civil society includes philanthropic foundations, labour unions, business forums and associations, professional associations, academic institutions, think tanks, religious groups and organizations, social and recreational clubs, cooperatives and community groups, environmental movements, lobby groups, women's networks, youth associations, relief organizations, and media outlets. Political parties are excluded if it is viewed that civil society organizations should not seek public office (UNDP 1997; Emmerij et al. 2001; Scholte 2005). In health governance, academic institutions, professionals, and professional organizations in public health have a unique and critical function. The public health community has been at the forefront of advocacy and in empowering civil society, by: (1) presenting evidence of health issues, and effective interventions; (2) demystifying technical subjects and the complexities of government systems and policy processes, by providing information to the public; and (3) facilitating engagement of members of the community. Civil society is the intermediary institution between the individual and the state and has a critical role in providing the checks and balance on government power and demands for greater accountability and transparency of public office. Civil society networks facilitate social and political interaction and communication. Civil society groups and organizations are effective channels of communications between individuals and business and the state, and are powerful groups for influencing public policies, and allocation of public resources that better reflect community needs. The origins of governance can be traced to civil society. Individuals in society group to take collective action, and deliver collective solutions in pursuit of common goals. Collective behaviour may be based on expectations and understanding of members of the group and rules and procedures may be informal. They may also be more organized with structures and agreed mechanisms for decision and criteria and procedures for membership. The range of arrangements from the informal to the formal depends on the purpose for which the group was created, the dynamics between members, and the context of the wider community environment. Many of the groups will cease after they have accomplished the goals for which they were created, or have been unable to make much progress, or members have lost their initial interest. A number will continue to develop and agreements and rules become institutionalized, and may even become legal entities—NGOs. NGOs may establish alliances among themselves or with other members of civil society, private and public sector agencies, to strengthen their influence and further their goals. These alliances may be temporary or may evolve into policy networks and other more formal arrangements. Linkages may also be established with international NGOs, particularly those with similar missions. The historical roots of present government emerged through these societal arrangements and developed over the millennia. Governance systems, like all complex systems, comprise components, or subsystems which are interrelated. The interactions and interrelationships of the principal components of governance systems are dynamic, with feedback which enables emergent forms to evolve. This is evident in the emergence of the powerful influence of the private sector and civil society in contemporary governance, particularly in global space. The instruments of influence of civil society are similar to

those of the private sector: exhortation, resource, and provision. In addition, it has a long-standing tradition of hybrid governance arrangements with government, particularly in implementing regulatory functions of the state. In many states, welfare benefits are contracted to NGOs, which are given the leeway to interpret criteria to determine the eligibility of applicants, such as in the eligibility for admission and transfers to nursing homes. Civil society actions in advocacy campaigns, public demonstrations, policy briefs, investigative journalism, and public interest lawsuits have become established tools for exhortation. In extreme circumstances civil unrest and disobedience may result in government backing down on unpopular policies, or may even lead to changes in government. In a World Bank paper entitled *Demand for Good Governance in the World Bank: Conceptual Evolution, Frameworks and Activities* (Demand for Good Governance Team 2010), demand-side governance tools which seek to empower civil society in its governance role are categorized under: (1) transparency and information, (2) accountability, and (3) participation. Tools in the transparency and information category include provisions for disclosure of relevant documents, right to information legislation, and mechanisms to demystify technical papers, and dissemination of information. Accountability tools include grievance redress mechanisms which can be formal, such as complaints office, appeals committee, ombudsman system, and local courts, and informal arrangements such as citizen grievance committees. Accountability tools can also be in the form of third-party monitoring of public sector activities and independent verification of outcomes of public policy, such as public service surveys and consumer satisfaction and client feedback surveys. In the third category of demand-side governance tools, mechanisms to enable participation include user committees and training and capacity building for stakeholder participation. Mechanisms to engage members of the community are necessary complements in the application of these tools, to recruit, mobilize, and motivate individuals and groups to actively participate.

Government

The structure for public health governance at the national level is determined by basic dimensions in government structures. In federal forms of government, such as in Canada, Australia, Germany, India, and the United States, the provinces or states share power with the federal government. The provisions in the Constitution delineate the authority and responsibilities of the federal and provincial government. The responsibility for financing may be a federal function and provision of services and regulation of providers a provincial or local function. Interpretation of the constitutional provisions may be contentious and may be challenged and subjected to adjudication by the courts, as in the recent example of the ruling by the Supreme Court on the healthcare reforms proposed by President Obama which mandated healthcare insurance for all individuals in the United States. In Canada, by Constitution, the majority of healthcare responsibilities were given to the Provinces, but the provisions for public health were not clearly allocated. Public health was considered to be under provincial jurisdiction under a section of the Constitution which gives the provinces property and civil rights, and subsequent legal interpretations have recognized this. This has created a dilemma for the federal government, which has resorted to other provisions in the Constitution to pass legislation to protect the public's health, such as in the control of

transmission of health risks (Wilson 2004). The ambiguity creates challenges in the coordination of public health responses, as each province has the authority to enact policies and pass legislation as it deems appropriate. Gaps and duplications in carrying out public health functions are potential problems (Office of the Auditor General of Canada 1999). Similar issues of jurisdictional clarity between different levels of government in responding to public health emergencies were also reported in an analysis of federalism, rights, and public health laws in Australia (Bennett 2009). Variability in standards of public health practice in these jurisdictions where public health responsibilities are primarily located in the provinces may also raise concerns. In nations with federal systems of government, public health institutions may be under the jurisdiction of different levels of government and accountable to elected officials of different political affiliations, with the potential for conflict. In unitary forms of government, all the powers reside at the national level and are delegated to the provinces and local levels as the government in power sees fit. In systems of unitary government, coordination of public health responses and conflicts between central and provincial and local governments does not have the constitutional and political challenges of federal forms, although there may still be problems from the organizational and managerial contexts. Another basic dimension of government structure which is a critical determinant of governance structure is the separation of executive, legislative and judicial powers. In Presidential systems, the chief executive and legislature are elected separately, and legislation and budgets proposed by the executive have to be passed by the legislature which also has the function of oversight of executive actions. Governance responsibilities and structures are constructed to reflect this. Designated committees in the legislature to debate, discuss, scrutinize, amend, endorse, or reject proposed public health policies are a usual structure. In parliamentary forms of government, such as in England, Singapore, and Malaysia, where the chief executive is chosen by the legislature, although budget, legislative, and policy proposals are also debated and have to be passed by the legislature, in practice the passage is usually achieved as the chief executive is normally chosen from the ruling majority and has its confidence and support. An independent judiciary is important, to ensure that the government of the day acts within the law and does not exceed the powers provided by law, and to ensure that laws are justly and fairly applied. The judiciary also adjudicates on constitutional issues between the different levels of government and between the people and the state, protecting the rights of the individual as enshrined in the constitution and other laws of the land. It has also an important function of interpreting laws. Many important public health policies are enacted in law, and the courts have been called upon to adjudicate when parties affected by public health policies believe they have been aggrieved by the enactment. The legal challenges by the tobacco industry to delay, subvert, and undermine public health legislation intended to reduce smoking have been well documented (Brandt 2007; Weishaar et al. 2012). The basis generally used to justify public health regulation is the 'harm principle' which was originally framed for medical treatment and services, which is that 'the law should only intervene in an individual's choice and behaviours only where those choices or behaviours pose a risk or harm to other persons' (Gostin and Gostin 2009). Legislation providing for the detention and quarantine of individuals, in the control of communicable diseases,

was premised on this principle. However, more recent legislation which aimed to control injuries and non-communicable diseases overrides individual choice for the protection of the individual and that of the population. The argument put forward is that governments have an ethical mandate to intervene to protect individuals and populations at risk of harm; the consequence for not doing so would be greater illness, and health inequalities which would divide communities (Gostin and Gostin 2009).

A feature of both federal and unitary forms of government is the structure of the executive branch, comprising a political and an administrative arm. The political structure is under the leadership of the elected chief executive, the President, or the Prime Minister and is supported by a cabinet of ministers who have responsibilities for different portfolios. Individuals, experts in their fields and external to the cabinet, may also be appointed to serve as 'national advisers' in providing input in specific areas considered necessary. Advisory boards and councils composed of experts and/or representatives of different professional and community groups may also feature as part of the mechanisms of the governance system that seek to interact with civil society. In federal systems, the structures are replicated at the provincial level. The Minister for Health is the cabinet minister who assumes responsibility for public health. The civil service normally houses the administrative arm. The cabinet ministers are supported by the civil service department heads of the respective portfolios, and different designations are given to these officials. In the public health portfolio, the lead official could carry a title such as Chief Medical Officer or Permanent Secretary for Health. The corresponding department would be the Department of Health, which provides support to the minister in: formulating health policies; developing strategies; assessing health needs and determining priorities; defining regulatory frameworks; commissioning, monitoring, and evaluating public health programmes; and collecting and seeking health data, information and intelligence. At all levels of government, horizontal structures are required for coordinating functions and interacting with and engaging the principal partners in governance, the private sector, and civil society. Many of the socioeconomic determinants of health are not under the policy responsibility of the health minister. Efforts to address health inequalities require cabinet action under the leadership of the chief executive. The health minister needs to work across cabinet colleagues and secure the support of the chief executive to give priority to public health strategies and programmes. At the administrative level, cross-departmental structures and processes need to be in place to coordinate the work required. In the political context of a government with a policy for democratic participation, and a recognition of the need for public health governance to incorporate political and public accountability, the Public Health and Health Professions Department of the Welsh Assembly Government is developing an integrated system of governance to improve public health (Jewell and Wilkinson 2008). The structures designed for cross-departmental collaboration comprise a permanent secretary's business group for all the heads of departments in government to meet on a weekly basis, and a strategy delivery and performance board for corporate decisions. The model of integrated governance for public health incorporates mechanisms and structures of interaction with: (1) the Welsh Ministers and local government, (2) regulators, (3) media, (4) voluntary sector, (5) public, (6) individuals, (7) professions, and (8) United

Kingdom and global policy. The interactions with regulatory bodies focus on strengthening the collaboration and coordination between the bodies inspecting, regulating, and auditing health and social care. At the local level, community governance is evolving as the roles and functioning of local government are changing as with the other levels of government. There is recognition of the need to engage citizens and communities in decision-making on the design and delivery of local social services in order to benefit from local knowledge and networks (Pillora and McKinlay 2011). A development in community governance initiated by the UK government was the introduction of a Localism Bill in the year 2000, which provided for 'community budgets', which would enable communities to have more control of their funding streams, enabling them to combine different sources of public funding to tackle cross-cutting issues in a particular locality. This revolutionary initiative of enabling local control over local spending would be pioneered in different areas in the country, with the aim of making it available throughout the country in 2013 (Pillora and McKinlay 2011). Strong civic leadership has been identified as a key component of community governance, required to mobilize communities and external stakeholders. New methods of community engagement involving active collaboration between groups with different knowledge bases are more likely to be successful and could facilitate the development of long-term alliances among members of the community from different backgrounds and affiliations. The policies and innovations in empowering and enabling civil society of local communities and service users to participate in policy options for services and resources has also been referred to as citizen-centred governance (Barnes et al. 2008). The fundamental change in community governance requires innovations in the mechanisms of enabling local communities to prioritize their needs, and how these needs will be met and public sector services improve the quality of their lives. The new mechanisms to involve individual members of the community and service users, and NGOs and community organizations are both in consultation and decision-making processes. The participation could be through formal appointments to community boards, management committees and as governors to National Health Service Foundation Trusts, serving alongside other private and public sector members. To strengthen local accountability, the National Health Service has innovated a new form of public organization, a 'public benefit corporation'. The foundation trust is structured to include three constituencies—the public, patients, and staff. Each constituency elects governors to represent their interests. Twenty-four of the 33 governors are elected by the three constituencies. Nine of the remaining governors are nominated by key stakeholders of the trust, the local authority, primary care trusts, and the university. The specific responsibilities of the governors include participating in the appointment of the trust's chair, non-executive directors, chief executive, and auditors. The governors meet in a consultative council and comment on the plans of the board of directors, the accounts, and annual report of the trust. A separate board of directors of executive and non-executive members is responsible for the strategic management and operations of the trust. There are also other forms of innovative governance which do not have a formal legal status, such as partnerships of public, private, voluntary, and community sectors in an 'unincorporated association' whose finances and contracts are managed on its behalf by a legally incorporated authority, trust, or agency (Barnes et al. 2008).

These innovations in governance which benefit from local knowledge are of particular relevance for disadvantaged communities and for implementing programmes to address poverty, social exclusion, and inequality, all key issues for public health.

The instruments used by government to influence society have been classified in a range of approaches, using different criteria. A classification by Hood (1986) groups these by government resource, namely nodality, authority, treasure, and organization. Another classification by Deber of policy instruments of government, is based on the degree of coercion in the means utilized. In this classification, the means of government influence from the least coercive to the most coercive are: exhortation, taxation, expenditure, regulations, and public ownership (Deber et al. 2004). Exhortation is often the first instrument used by government in governance, seeking initially to persuade with information and rationale (and may also include inferences of more coercive action if this does not have the effect intended). Health messages and information on health risks, interventions, and services are examples. This is frequently accompanied or followed by more coercive instruments, such as expenditure for a comprehensive programme of health education. Taxation is viewed as only slightly coercive. Providing tax incentives or disincentives, encourages or discourages targeted behaviours respectively. Provision of tax exemptions for not-for-profit organizations has encouraged the growth of NGOs in civil society, many of whom are engaged in social and health endeavours and services. Charities and charitable foundations are exempted from tax and in most countries make a substantial contribution to health initiatives. Tax disincentives, such as tax on tobacco and tobacco products, have been effective in reducing smoking rates. Expenditure is considered moderately coercive. This financial instrument can be cash or in-kind support such as providing meeting rooms for patient groups, and organizations to conduct patient support programmes. Contracts and direct payments to NGOs to operate health services and programmes for the care, treatment, and support of patients with HIV/AIDS, would be an example of the use of this vehicle. Indirect means can also be used, such as subsidies for vaccines to encourage uptake of an immunization programme to prevent an outbreak of seasonal influenza. The use of vouchers has also been used to improve access and encourage utilization of health services. The fourth category of instruments, regulations, is more coercive. The definitions of regulations used are 'all mechanisms of intentional and unintentional control' (Saltman and Russe 2002), 'setting rules of behaviour backed up directly by sanctions and penalties of the state' (Doern and Phidd 1992). Powers of regulations accrue to the three branches of government, the executive, legislative, and judicial, and can be in the forms of administrative decree, legislation, and judicial orders. Regulations on drugs and biological products seek to protect the public, ensuring the safety and quality of these products. The regulatory function may be administered by the government directly or by a public agency, such as a National Drug Administration or Agency. Regulation of health professions has been assigned by the state to the professions, in state-endorsed self-regulation, which is usually backed up by sanctions normally available only to governments. This hybrid form of governance arrangement, in which the private sector is able to use instruments of the state, is one instance of the evolving environment of health governance. The potential benefit of this arrangement is that the professional knowledge of

a group of peers will enable effective ways of regulating conduct and behaviour and should reduce the cost of compliance, as compared to having government regulating. The disadvantage is the potential for 'regulatory capture' when professions use the process to protect their own interests over the public's. The fifth and last category of policy instruments in Deber's classification is public ownership. This is seen as the most coercive as government has 'full' control of the organization, product, or service it owns or provides. A National Health Service, providing health services to all the citizens of the country, enables governments to determine the types, scope, quality, and quantity of health services available, and where they will be available and how they will be accessed.

The policy instruments of government are one of the principal categories of the instruments of public sector governance; two other categories relate to structure and processes that foster coherence, collaboration, and partnership, within government and with civil society and the private sector (St-Pierre 2008). The cabinet of ministers of executive government is a key structure for coherence and consistency of national policies and intersectoral collaboration in policy development. Standing and ad hoc inter-departmental committees and task forces are structures within the administration which coordinate the work of different government departments. Structures for interactions and engagement with the private sector and civil society include advisory boards and consultative committees. New structures have been introduced to facilitate community- or citizen-centred governance, to engage the community in local governance. Examples of these include deliberative forums, citizens' juries, and community conferences (Pillora and McKinlay 2011). Networks of public officials with individuals, groups, and organizations in the private sector and civil society are a flexible structural mechanism for interaction. Participation in networks is voluntary; the interactions are informal and facilitate mutual understanding and development of common goals (St-Pierre 2008). The more recent innovative hybrid structures of 'unincorporated associations' of partnerships of the public, private, voluntary, and community sectors, is an organizational form. Appointment of community members and organizations are also structural forms of governance instruments. The third category of governance instruments of the government is processes (St-Pierre 2008). Different approaches to engage the community are needed to mobilize participation. In the United Kingdom, public and patient members for the constituency for governors in the National Health Service are advertised.

Supranational health governance

Health governance at the supranational level comprises three configurations: (1) an international configuration formed by a voluntary agreement of national governments and governed by formal rules of engagement, decision-making procedures and conduct, typified by organizations such as: the UN and the agencies within its ambit such as UNDP, and WHO, and a host of other international organizations such as World Bank, International Monetary Fund, World Trade Organization, G8 and G20; (2) regional groupings of sovereign states governed under different mechanisms and arrangements, ranging from the most formal, the European Union, with a formal constitution within which member states are obliged to act, to geo-political groupings of nations for economic and security discourse and agreements, such as Asia Pacific

Economic Cooperation, North Atlantic Treaty Organization and the Association of South East Asian Nations; and (3) a transnational global formation, comprising not only international and regional organizations and nation states, but also transnational and multinational business corporations and social movements and organizations of civil society. The challenges and issues in global health and the global health governance have generated considerable discourse and research, not only in public health, but also in international relations, political and social sciences, and international law. Global health and how it is governed affects every nation on the globe and the health of all of humanity.

Globalization, an intensification of the connections between populations enabled by the growth in the flows of people, goods, services, and ideas across countries, has been associated with a concomitant globalization of health determinants (Dodgson et al. 2002; Magnusson 2009; Kruk 2012). The health of populations has improved indirectly due to the benefits of globalization on the broader social determinants, although the benefits have not been spread equally within populations and between nations. In parallel, with globalization the transnational nature of the risk of infectious diseases associated with the increased flows of people and goods has been well documented, exemplified by the spread of HIV/AIDS in the last quarter of the twentieth century and of SARS in 2003. Although not receiving the same attention, there has also been globalization of risk factors for chronic diseases (Magnusson 2009). Non-communicable diseases accounted for 59 per cent of global mortality, with 54 per cent of all deaths in low- and middle-income countries, and 87 per cent in high-income countries. Economic growth is increasing incomes, urbanization, and a trend to more sedentary lifestyles. Intense global marketing of processed foods with transnational investments in supermarkets has also been associated with a change from traditional to diets richer in salt, sugar, and fats. The marketing of tobacco globally is hampering the efforts of national governments to control its use to reduce the harmful health effects. Climate change, an ecological impact of environmental change, is global. The global nature of health determinants restricts the capacity of national governments to address them on their own and international and global strategies are required. Global health, and its priorities, policies, and governance, are defined by the metaphors of how global health is framed. At least five metaphors have been identified. Global health framed as foreign policy is based on politicians using global health policies to foster trade, alliances, economic growth, stability, and democracy. The priority diseases targeted would be infectious diseases and HIV/AIDS. The second metaphor frames global health as security, the goals would be to combat bioterrorism and infectious diseases. Priority diseases targeted would include avian influenza, AIDS, and multidrug-resistant tuberculosis. The third frame is as charity, with the goal of fighting absolute poverty. Priority diseases to be addressed would be malnutrition, HIV/AIDS, malaria, and tuberculosis. The next frame is as investment, and how to maximize its value. Priority diseases would be HIV/AIDS and malaria. The fifth metaphor frames global health as public health, the goal would be to maximize health effect. The priority would be reducing the worldwide burden of disease (Stuckler and McKee 2008). In a discussion of the concept and definition of global health, a consortium of universities advocated that global health should also address tobacco control, micronutrient deficiencies, obesity, injury prevention,

migrant-worker health, and migration of health workers (Koplan et al. 2009). They also drew a distinction between global health, international health and public health. As discussed, how global health is framed will define policies, priorities and governance. On this premise alone, global health must be public health. The challenge of how this could and should be addressed has stimulated debate on global health governance. The policies and programmes to address transglobal risk factors for chronic diseases effectively are beyond the capacities and mandates of national governments on their own. Strategies and policies to address changing dietary habits require engagement with the food system, from primary production, manufacture, through to retail, catering, and advertising, agriculture, and trade, at national and international levels.

In the last one and a half decades, there has been a substantial increase of stakeholders in health with considerable influence on the global stage, and a consequential change in the configuration of the relationships, roles, and influence of the civil society, the private sector, and the state in health governance. Development Assistance for Health (DAH), defined as all disbursements for health from private and public institutions whose primary purpose is to provide development assistance to low- and middle-income countries, grew from US\$5.1 billion in 1990 to US\$21.8 billion in 2007 (GFATM 2013). DAH rose sharply after 2002, both from public and private funding. The US government was the largest public source of donations, followed by the United Kingdom, Japan, Germany, France, Netherlands, Canada, Sweden, Norway and Italy. The financial flows from low- and middle-income countries including China, and non-OECD high-income countries were not included in the assessment. The increases from private sources, from both philanthropic foundations and donors, and in-kind contributions from the private corporate sector which included donations of equipment and drugs from the pharmaceutical industry, amounted to approximately 50 per cent of the total disbursements for most years. The sources of funding from private donors and foundations increased, accounting for a growing share of DAH, from 19 per cent in 1998 to 26.7 per cent in 2006. In 2007, the Bill and Melinda Gates Foundation (BMGF) alone, was estimated to have spent US\$2 billion on global health, comparable to the US\$3.3 billion budget of the WHO (Kruk 2012). Equally significant, the proportion of funds channelled through UN agencies and development banks decreased, while NGOs and the GFATM, and the Global Alliance for Vaccines and Immunization (GAVI) accounted for an increasing share of DAH (GFATM 2013).

The significance of the changes in the flow of funds is not only in the relative role of UN agencies such as the WHO and UNICEF, but the fact that these agencies have to compete with NGOs for a share of the voluntary contributions which make up a growing proportion of their total expenditure. The powerful influence of the private sector in the changing global landscape is also evident in the strategies and tactics employed by the private corporate sector. There is well-documented research about how corporate strategies and actions at local, national, and global levels hindered the development of comprehensive approaches to tobacco control (Weishaar et al. 2012; GFATM 2013). Global tactics were employed by transnational tobacco corporations to undermine the development of the WHO Framework Convention on Tobacco Control (FCTC) (Weishaar et al. 2012). The research was based primarily on internal industry documents made public through litigation in the United States and a comprehensive literature review of the

tobacco industry's strategies to influence the FCTC. The research demonstrated how the industry was able to develop and employ a comprehensive, multipronged strategy across multiple jurisdictions at a global level (for further detail, see Chapter 9.1). They highlight the flexible and varied approaches used by the industry, often ahead of the efforts of a weak system of international health governance, which is dependent on the voluntary participation of national governments and on their capacity to implement approaches they have committed to, in their respective states.

In the discussions of chronic disease and the challenge of global health governance, Magnusson also examined the nature of international health law and draws a similar conclusion: 'International health law, where it exists, takes the form of international agreements whose substantive obligations nation states have signed on to voluntarily, following a process of negotiation in a multilateral forum'. An important exception is the International Health Regulations (IHRs), which binds members on an 'opt-out' rather than an 'opt-in' basis (Magnusson 2009). The pace and extent to which individual states execute national policies to meet their substantive obligations is determined largely by the capacity and political commitment of the state, the only external influence is the normative pressure brought to bear by the international and global communities, notably, civil society. Understanding the prominent roles of the multinational corporations, and of civil society in global health requires an examination of the global governance environment. Many scholars from different fields have engaged in this pursuit.

Jan Aart Scholte puts forward the notion of globalization as 'deterritorialization' or 'supraterritoriality', and 'globality' as a unique social space, that transcends territorial place, distance, and borders, where there is no single source of authority (Scholte 2005). Geographical territoriality is determined by sovereign statehood which has jurisdiction over a designated territorial space. He goes further, arguing that territorialist governance is no longer practicable as national governments are no longer able by themselves to regulate effectively in the face of global mass media, ecological challenges, and finance. In this global governance space, unfettered by the absence of a 'world government', the roles and influence of the non-state institutions of society, namely the private sector and civil society, are transformed from those in sovereign states. In the absence of a single source of authority, the powers and influence of the corporate sector and civil society are considerable and arise from: (1) the resources at their command, (2) the capacity to frame and influence global health issues, (3) the flexibility in regularly incorporating new organization forms for governance in response and in anticipation of the rapidly changing environment, and (4) the ability to capitalize on new hybrid structures of partnerships of private-public governance which make available traditional public sector instruments for governance (Rosenau 1995; Kickbusch 2002; Loughlin and Berridge 2002; Kohlmorgen 2005; Scholte 2005; Kruk 2012). In contrast, the powers and influence of the state are muted. The traditional structures for governance of the state are lacking, the instruments of the state are also blunted, acting primarily through international bodies, the effectiveness of which has been limited. Fidler refers to the phenomenon of 'old-school anarchy' to describe the environment of international governance in which collective action taken by states is characterized by protracted negotiations, as states generally prefer to limit their obligations and restrictions

to their sovereignty, and retain greater flexibility to pursue their own national priorities and interests (Fidler 2007). Fidler concluded that there was not a single global governance structure or distinct architecture and coined the term 'open-source anarchy' for the governance space which is equally accessible to state and non-state actors. The overlapping roles of international agencies in health governance have been significant and compound the phenomenon of the fragmentation of the influence of nation states in international and global health governance. The World Bank, WHO, and UNAIDS are three different forms of intergovernmental organizations with overlapping roles in global health governance. This governance space of open source anarchy, which is not under the jurisdiction of sovereign states, presents unprecedented opportunities for stakeholders in the global stage to define the new world order. The private corporate sector is the most powerful entity in the current environment of global health governance (Kempa et al. n.d.), with its flexibility to adapt to the changing terrain, entrepreneurial capabilities to innovate new mechanisms for influence, and market expertise to capitalize on the untapped potential in this new governance space. Even international organizations and states are capitalizing on the global 'open space anarchy' to further their own interests. In addition to its international role in global health governance, the United States has also taken bilateral, multilateral and unilateral roles. The United States provides one-third of the total bilateral global aid to health (Ollila 2005). One recent prominent example of its many roles is the President's Emergency Plan For AIDS, launched in 2004 providing US\$15 billion over 5 years to fight HIV/AIDS; US\$9 billion for new bilateral programmes, US\$5 billion for existing programmes in 75 countries and US\$1 billion for the GFATM (Kohlmorgen 2005). The unilateral role in global health and the links with its own domestic policies and interests and repositioning, has been the subject of some discussion (Kickbusch 2002). The United States is not unique in its multiprong approaches in global health. Many wealthy nation states are active in bilateral aid, including the more recent additions of India and China. Many multilateral initiatives of the powerful states either on their own or in partnership with private foundations and corporations have proliferated (Kickbusch 2002; Kohlmorgen 2005). Global health governance has been characterized as unstructured, pluralistic, and multicentric (Kickbusch 2002; Ollila 2005; Kruk 2012). The role and influence of private foundations and multistakeholder initiatives in defining and funding global health priorities has gained prominence in the last two decades. Kruk reported that there are now 100 GHIs, multistakeholder initiatives generally focused on a specific disease, product, or population, such as the GFATM, GAVI, and US President's Emergency Plan for AIDS Relief (PEPFAR). This has been paralleled by the emergence of major, extremely well-resourced GHIs by private foundations, such as the BMGF, the Clinton Foundation, and the Rockefeller Foundation (Ollila 2005; Kruk 2012). The plethora of GHIs has generated discussions about how these should be governed, and about global health governance in general. The issues of concern pertain to: (1) the composition and governance of the different GHIs and partnerships, their representative legitimacy, accountability, competence, and transparency in the decision-making process; (2) GHIs may differ from national health priorities; (3) the limited capacity of the health system infrastructure in many developing countries requires augmentation to enable delivery of the global health

programme; and (4) the transaction costs of applying for funding from the different funds, the burden of planning for the dissimilar programmes, and the need to meet the requirements of multiple donors in reporting progress, and financial and management information and evaluation methodologies (Brugha and Walt 2001; Ollila 2005). In recognition of these issues, efforts have been made to coordinate the global programmes. Health 8 (connotations of G8) comprising a grouping of GHIs and international agencies: WHO, World Bank, UNICEF, UNFPA, UNAIDS, GAVI, GFATM, and BMGF and International Health Partnerships, a grouping of seven donor countries, were formed as informal partnerships to facilitate coordination (2012). Global health governance is multicentric, with multiplicity of stakeholders' interests defining multiple frameworks (Hill 2011) and characterized as unstructured plurality (Fidler 2007). New governance forms of public-private partnerships of international bodies and agencies, national governments, civil society, and transnational corporations have emerged (Magnusson 2009; Hill 2011). Hill discusses global health governance as a complex adaptive system, with rich dynamic interactions, non-linearity of the relationships, and the relative interdependence of other elements within the system (Hill 2011). Studying global health governance as a chronic adaptive system provides a model for deeper understanding of the relationships and interactions of the components and the capacity to track, study, and research the changes that will emerge and evolve, reminiscent of the phenomenon 'back to the future', how governance evolved through the millennia to its form today of government, civil society and the private corporate sector.

Good health governance

Governance is a neutral concept. The UNDP defines it as the exercise of political, economic, and administrative authority in the management of a country's affairs at all levels (1997). It is how the authority is exercised which is the basis of good or bad governance. The UNDP has identified eight attributes of good governance, namely: participation, rule of law, transparency, responsiveness, consensus oriented, equity and inclusiveness, effectiveness and efficiency, and accountability.

The World Bank's approach to identify good governance is based on measurement of subjective perceptions of a set of over 300 governance indicators, in polls of experts and cross-country survey of residents. The World Bank's definition of governance is 'the traditions and institutions by which authority in a country is exercised' (Kaufmann et al. 1999). This includes '(1) the process by which governments are selected, monitored and replaced, (2) the capacity of the government to effectively formulate and implement sound policies, and (3) the respect of citizens and the state for the institutions that govern economic and social interactions among them' (Kaufmann et al. 1999). These were used to organize a subset of governance indicators into six clusters. Two clusters under the titles 'Voice and Accountability' and 'Political Instability and Violence' are key aspects of 'the process by which governments are selected, monitored and replaced'. The next two clusters titled 'Government Effectiveness' and 'Regulatory Burden' are aspects of 'the capacity of the state to formulate and implement sound policies'. The final two clusters under 'Rule of Law' and 'Graft', are derived from 'the respect of citizens and the state for the rules which govern their interaction'. The data was collected

from over 150 countries. The quality of governance was correlated with developmental outcomes in cross-country comparisons. The study concluded that there was 'empirical evidence of a strong causal relationship from better governance to better development outcome' (Kaufmann et al. 1999).

In health governance, a recent attempt to identify the attributes and indicators of 'good health governance' was made by the Eastern Mediterranean Regional Office of WHO, in conjunction with Johns Hopkins University, Pakistan Health Policy Forum, Heartfile, and the Country Office of WHO in Pakistan. The goal was to develop a framework for assessing health governance as a gateway for good governance of health systems (Siddiqi et al. 2009). The group studied four frameworks developed for analysis of national governance, namely the UNDP's principles of good governance, the World Bank's six basic aspects of governance, the Pan American Health Organization's (PAHO) essential public health functions, and the WHO domains of stewardship. The group examined the PAHO's 11 essential public health functions in developing the framework because they were based on the principles of public health, and included the collective intervention of the state and civil society to protect and improve the health of the population, and the responsibilities of the steering role of government. The WHO in the *World Health Report 2000*, recognized stewardship of health systems as a key responsibility of the government (WHO 2000). The group concurred that the concept of stewardship is very similar to governance and that the terms were used interchangeably, but the group preferred the term 'governance' as the performance of health systems depends on overall governance of a country, and the many international development institutions and agencies had delineated attributes of governance that were understood and had been applied in assessment of governance, and governance is more familiar and better understood. The three stewardship tasks—defining the vision and direction, exerting influence, and collecting and using intelligence—were also governance functions and were included in the analysis. The group concluded that the UNDP governance principles provided a useful basis for developing the analytical framework for assessing health systems governance as it enabled a direct approach for the purpose and tools could be developed for more in-depth assessment. However there was a need to adapt the approach to include aspects unique to health. This was achieved by incorporating health-specific components of governance embodied in the stewardship functions proposed by WHO and PAHO's essential public health functions. Some aspects of the World Bank's principles of governance were also incorporated. The group proposed ten governance principles for assessing health governance: strategic vision, participation and consensus orientation, rule of law, transparency, responsiveness, equity and inclusiveness, effectiveness and efficiency, accountability, intelligence and information, and ethics. The ten principles were subsequently disaggregated into domains, from which were derived broad questions, leading to specific questions. The approach permitted an expression of the full meaning of the principle and how it could be operationalized. A total of 63 broad questions were developed and were related to context, description, process, and outcomes. The assessment framework has been applied to low- and middle-income countries

Stewardship, governance, and good governance

As discussed earlier, the concept of stewardship and governance in the WHO documents are similar and used interchangeably. In the conceptualization of health governance by the WHO, 'Governance in the health sector refers to a wide range of steering and rule making related functions carried out by governments/decision makers as they seek to achieve national health policy objectives that are conducive to universal coverage' (WHO 2013). The WHO's approach to health governance has evolved from the concept of stewardship in the *World Health Report 2000*, which was defined as a 'function of a government responsible for the welfare of the population, and concerned about the trust and legitimacy with which its activities are viewed by the citizenry' (WHO 2000). In a subsequent publication in 2007, *Everybody's Business: Strengthening Health Systems to Improve Health Outcomes*, 'leadership and governance of health systems' are 'also called stewardship' (WHO 2007). It is about the role of government in health and its relation to other actors whose activities impact on health. Health governance and public health governance as defined (Bennett et al. 2009), is the collective means adopted by society in attaining the conditions for health, and recognizes the partnerships of civil society, private sector, and the state in governance. In this conceptualization, stewardship described by WHO is in fact the Health Ministry's role and function in the context of government's responsibilities in the tripartite governance model. The stewardship role of government in health governance is to oversee and guide the whole health system in improving the health of the population. In fulfilling its responsibility as stewards in health governance, WHO has identified six key functions for stewardship as follows (WHO 2007):

1. Policy guidance: defining goals, directions and priorities, developing strategies, and establishing the roles of the public, and private sectors and civil society.
2. Intelligence and oversight: on responsiveness, financial protection and health outcomes of the health system, policy options, effects of policies and reforms, and on trends and differentials in inputs, access, coverage and safety of health services.
3. Collaboration and coalition building: across government, and with civil society and the private sector, to facilitate action which improves health and to generate support for health policies.
4. Regulations and incentives: should be designed, and fairly enforced to support strategies, goals and priorities.
5. Systems design: to ensure a fit between strategy and structure, minimizing duplication and fragmentation.
6. Accountability mechanisms: to be applied to all the components of the health system, transparency being a prerequisite.

WHO's description of the attributes of how the role and function should be performed effectively spells out the 'Good Stewardship role of Government in Public Health Governance'. In a similar way, in the context of global health governance, the WHO would be an appropriate body to have the stewardship role from its mandate in international health.

Governance and management in public health organizations

Good effective management in public health organizations is critical for success in developing and implementing strategies and programmes to improve the health of populations. Two key characteristics of public health programmes that create the context in which the governance and management in public health organizations should be considered are: (1) the majority of public health programmes involve the public sector, and not-for-profit organizations, and community organizations and groups with a wide range of formal and informal governance arrangements and capabilities, and (2) public health programmes range in scale from transnational and international programmes and initiatives, such as the global programme for HIV/AIDS, to discrete local programmes to improve health knowledge in local communities.

This organizational context of public health organizations creates the need for: (1) different governance and management systems appropriate for the legal incorporation status, size, complexity, and organizational formality of the NGOs and community organizations and groups; and (2) different management roles for public health officers depending on how the programme was initiated (De la Peza and Perry 2010). The civil society organizations and groups could be: (1) established NGOs, legally incorporated with formal board structures and policies and procedures for how they function; (2) recently incorporated NGOs originating from a small group of volunteers committed to a social cause, and supported by a handful of staff; and (3) largely informal community groups and networks of community groups and organizations, the majority without legal incorporation, working collectively for a common objective

Governance in legally incorporated public health organizations

The Institute on Governance in its work with the public sector and not-for-profit organizations defines governance as processes and a set of practices which enable an organization to achieve its goals. This is a system that defines how authority, decision-making, and accountability are exercised, and within which the organization determines its directions, monitors performance, and allocates power and resources (Institute on Governance 2011). Management is the process of planning, organizing, leading, and controlling the efforts of organization members and of using organizational resources to achieve stated organizational goals (Longest and Darr 2008). Management and governance are integral aspects of an organization, and enable it to accomplish the objectives and goals for the purpose for which it was set up. Although the roles can be segregated and functions differentiated, they need to be understood as interdependent and interrelated components in the continuum of systems and processes of the organization. The ultimate powers, authority, and accountability reside in the governance function of boards of incorporated organizations, and in the exercise of its powers in defining how authority, decision-making, and accountability will be exercised, it must do so in a manner which enables management to function effectively and efficiently, to accomplish the goals and objectives set. Conversely, management also has a responsibility to support governance to fulfil its duties and obligations setting directions and in the design of

systems with the categories of information required for monitoring of performance.

The process of developing the governance system should commence with examination of the legislative framework under which it was incorporated. Depending on the jurisdiction, they may be required to register as voluntary organizations or societies or be legally incorporated under the company's ordinance, with corresponding regulations under which they are required to operate. The organizations whose mission is not-for-profit, which would be the majority of public health community organizations, would be eligible to apply for tax exemption status. This would impose additional legal regulations with which the NGO would have to comply. The articles of incorporation specify the powers, responsibilities, and roles of the general membership and of the directors. The structure, composition, and procedures for the formation of the board, and rules and procedures for conducting meetings of the general membership or assembly and appointments of officers such as auditors and legal advisors may be specified either in the articles of incorporation or in the bylaws under which the organization should operate. The articles of incorporation serve as the 'constitution' under which the organization functions, sections of which are legally mandated under the relevant governing legislation and cannot be altered. The sections that are optional are within the discretion of the members of the organization, but any amendments require the approval of the general membership. The bylaws supplement the articles of incorporation, defining the rules, processes, and conduct under which it operates. Compliance to both the articles of association and bylaws is required.

Function of the board of directors

The first function of the board of directors is to determine the structures and procedures under which it will operate, within the requirements of the law, to define the policies and conduct under which it will function, and the values which will guide decision-making.

The second function of the board is to clarify its roles and define how this will relate to the roles of the chief executive and management team, and determine the decision-making process.

The third function of the board is to define how it will fulfil its responsibilities by examining four aspects of governance (De la Peza and Perry 2010):

1. Setting direction—the organization defines the mission, the purpose for its creation, and serves to align the board, management, and staff, providing meaning for its work. The mission is supported by defining a shared vision, representing where the organization aspires to be and provides the focus for the development of a strategic plan.
2. Overseeing organizational effectiveness and providing support—involves appointing a chief executive officer with the attributes to lead the organization, competencies to implement policies and execute plans, capacities to work collaboratively with the board to enable the board to fulfil its responsibilities, and conduct and values compatible with the organization's mission. The board needs to ensure that: the decision-making processes in the organization are transparent, the organization's resources are used rationally, efficiently and effectively, financial oversight is effective, the organization is financially sustainable, and quality of services are continuously improved.

3. Maintaining good external relationships—strategies, structures and mechanisms need to be established to engage and communicate with the community, donors, partners, and the government. Stakeholders need to be informed, their expectations need to be met, and their support needs to be solicited.
4. Maintaining the effectiveness of the board—this is enabled by having a composition of members with the skills, experience, diversity, commitment, and integrity, supported by an education and development programme, effective board structures and processes, and a system for evaluating and improving board performance.

A fourth function of the board is to consider ‘intelligence systems’ that will enable understanding, encoding, and tracking of the ‘informal governance’ mechanisms which are present in all organizations. Informal governance refers to traditions, organizational values, founding principles, and culture that are typically unwritten but that nonetheless prevail in the organization (Institute on Governance 2011). These traditions and values have a significant impact on how decisions are made, and how the decisions are affected.

The governance system in smaller NGOs with limited human resources, scale, and scope of work, has to be designed to suit their requirements. In these organizations, transitioning from voluntary initiatives and shared commitment to a common objective and functioning with informal rules, to the formal organization environment of a legal incorporation requires substantial support. In the process of transition, the founders who have been intimately involved with every aspect of the endeavour may have difficulty in separating governance and management roles. Resultant gaps in fulfilling governance functions required by law may be even more problematic. Complex, elaborate mechanisms are inappropriate. Simplified models based on principles of good corporate governance, and appropriate external support from organizations in civil society with a mission to promote governance, such as the Institute on Governance, academic and training institutions, and foundations.

Governance in public health organizations lacking legal incorporation

The governance mechanisms of largely informal community groups and networks of community groups and organizations, the majority not legally incorporated, are structurally distinct. These collaborations and partnerships are based on voluntary participation and authority is derived from the consent of the members. A study of governance in public–private community health partnerships reported a wide range of governing characteristics in the 25 partnerships involved in the community care network (Alexander et al. 1998). The study concluded that: (1) there is no single best way of governing community partnerships, and (2) governance structures and progress towards governance goals could be related to organization, composition, location, and type of collaborative activity of the partnership. Effective governance in these networks have as their foundations a commitment to a shared vision of community health and leadership in the governing bodies, and building of trust in incremental steps which would be the basis of changing governance practices. The range of governance arrangements and practices reflects a developmental continuum of different pathways.

Some will evolve to more formal organizations with better alignment of the objectives of the remaining partners, a number will continue to operate under network governance based on commitment to a common purpose and trust, and a few may be disengaged either because the purpose of the collaborative partnership has been dealt with as far as it was possible under the arrangements or progress was not made with loss of interest among the members.

Governance–management collaboration

The management roles of executives and public officials in public health organizations in supporting and facilitating good governance of groups and organizations in civil society is one facet of the governance–management interdependence which is critical for effectiveness of public health organizations and programmes.

The interdependence of governance and management functions is evident in the need for collaboration between management and governance, to enable the board to fulfil its responsibilities and management to understand the organization’s mission and to be guided in its decisions by its values and vision. There are corresponding responsibilities of the board and management in developing the four key components of governance function of the organization in setting direction, overseeing organizational effectiveness and providing support, maintaining good external relationships, and maintaining the effectiveness of the board

Management of public health organizations

Management is the process of planning, organizing, leading, and controlling the efforts of organization members and of using all other resources to achieve stated organizational goals. Management has also been described as the science of getting things done through people. Management science is applied: (1) in the management of the organizations; (2) in the management of a function, for example, governance function in public health, ‘Public health management’; and (3) in the management of a task, project, or programme, for example, ‘Programme management in public health’.

General management principles apply to all organizations, but the application of the principles in the practice of public health also needs to be understood to enable effective management. Public health management functions in diverse contexts.

Public health management

Public health management, defined as ‘the optimal use of the resources in society and its health services towards the improvement of the health experience’ (Alderslade and Hunter 1994), has epidemiology at its core, and requires management capabilities and capacity. The conceptualization of the WHO has been driven by the knowledge that although significant health gains can be attained through systems and innovative approaches in health promotion and disease prevention, and by more effective management of clinical care, health systems are grossly underperforming in terms of improving the health of populations relative to what is feasible.

Another observation that has driven the approach is that the public health agenda has not been given the priority it should have, and this has been attributed to insufficient political commitment, marginalization of public health in health systems, and the limited capacity of public health to influence policymakers to make the changes necessary (WHO 2002). Public health management is based on the premise of a public health infrastructure, embedded in the health system, effecting interventions to improve the health of the population through the different components of the system in a holistic approach. This should enable health systems to be transformed from 'disease systems' to truly 'health systems'.

The principles of a public health management approach include (WHO 2002):

- ◆ 'Public health can find a legitimate place within an integrated set of provider services and hence be strongly supported within a provider framework.
- ◆ Critical to the success of this integration is strong central government commitment to public health outcomes for all provider services thus reinforcing the contributions public health can make to an integrated provider system.
- ◆ Contracting for outputs/outcomes, with ring fencing of public health funding, is one means of achieving this.
- ◆ Organized primary care is a key service division of an integrated district health system, with symbiotic relationships with public health.'

WHO has characterized the distinguishing features and roles of public health management (Table 6.8.2).

Public health management is a tool of governance that can bring about fundamental changes in the system at the national policy and local management level. At the national policy level the key considerations are: (1) developing a vision for coordinated 'joined up' policies in government which complement the policies to improve the health of populations, and for the vision to be effectively communicated and institutionalized in the decision-making structure; (2) ministerial leadership role in influencing other relevant government ministries and departments; (3) systems, mechanisms, and processes for integrated policymaking and implementation; and (4) cross-service and cross-agency collaboration for horizontal

integration at local, provincial, national, and supranational levels and integration of these levels.

At the local operational level, the key considerations are: (1) developing and implementing a national policy framework which adopts a health outcome focus, (2) organizational options for coordination of providers and networks, (3) funding models to enable public health focus in integration, and (4) strategic purchasing and management. New Zealand is an example of a country which has an integrated system which is based on a broader conception of public health. Public health remains a central component of an integrated provider system, linked to primary care. All services—primary, secondary, and traditional public health—are population based (WHO 2002).

Programme management in public health

Programmes in public health range in scale and complexity, from global and multinational programmes and initiatives such as the multibillion GFATM covering specific country-level programmes in different nations across the globe, to discrete modest initiatives of local NGOs to improve health knowledge. Different governance structures and mechanisms are required for these two extremes of programmes, and the management approach would have to be tailored accordingly. However, principles of programme management apply to both.

The objective of programme management in public health is to organize and direct public health workers in the implementation of scientifically sound interventions, and appropriate strategies towards specific health problems (Bernard and Turnock 2013). The approach seeks to integrate the knowledge in public health with the scientific approaches in management in planning, organizing, leading, and controlling interventions to improve health. Success of a programme is not judged only by the programme's goals to improve health but also by criteria of efficiency and effectiveness. The programme management cycle comprises planning, implementation (organizing and leading), and evaluation (controlling). The three management processes should not be viewed as discrete phases, since feedback at all stages of the cycle should be used to make appropriate changes to the plans. There are continuous changes in both the internal and external environment,

Table 6.8.2 Distinguishing features and roles of public health management

Distinguishing features of public health management	Roles of public health management
Is multisectoral and professional	Advocacy and management roles
Combines knowledge and action	Knowledge and action
Has epidemiology at its core	Managerial capacity and infrastructure
Is influential across all health determinants	Networking to create partnerships across organizations and disciplines
Involves public health reporting, leading to health strategy development	Broad involvement of people and skills
Communicates with politicians, professionals, and the public	Infrastructure and curricula for education
Is influential organizationally and financially	Evidence-based policy and practice
Lies at the heart of the civic society	An outcome-based focus
	A national agenda for health and health services research

which have an impact on the planned intervention and require a modification of implementation strategies. The strategy for evaluation should be considered at the planning phase, based on identifying measures which would enable assurance of attaining critical milestones throughout the programme management cycle.

The approach to programme management can be framed in terms of asking five key questions: (1) Where are we? This involves examining the state of the current problem, identifying the effective interventions available, and the resources available; (2) Where do we want to be? This is the desired outcome to be accomplished; (3) Should we do something? This requires a decision on the extent of a health problem that warrants intervention; (4) What should we do? This is the process of establishing a work plan that incorporates the tasks and activities that are required, the resources that need to be committed and measures to track progress. This would also lead to development of a programme budget and the process of organizing the intervention. Programme structure, systems, and processes need to be designed, responsibilities and accountabilities assigned, and coordination and control mechanisms built in; and (5) How do we know that we are getting there? The key is to establish measurable milestones in time and direction that assure that the tasks are on track, the process objectives are achieved, and the intended health outcomes are attained.

Management in public health organizations

The four management processes of planning, organizing, leading, and controlling can be applied to every organization and facilitate the achievement of organizational goals (Longest and Darr 2008). Planning refers to deciding what to do, what is to be achieved, strategies for the task, and committing the resources required. Organizing is the design of an organization to execute the plans by establishing work units/clusters, allocating resources (including human) and responsibilities, delegating authority, establishing accountability, coordination of work processes, procedures, communications, as well as integration of work produced, systems, and structures.

Leading means leading, directing, and motivating people in the organization to achieve its plans and objectives. The last management process on controlling is to ensure the organization, work plans, and objectives are achieved through establishing and measuring performance standards, detecting deviations, and correcting performance. Not-for-profit (NGO) public health organizations vary considerably in their mission, scope of operations, and complexity of organization. Smaller NGOs have limited management and governance capacities. Board members may be volunteers who have a strong sense of purpose, and a hands-on approach to the operations. Conversely, boards may have evolved with time from the original founders and may not be able to commit the time to fulfil good governance requirements. The role of management to support the board to enable it to perform its function and fulfil its responsibilities is crucial. Good management will understand that an effective board in fact facilitates its work. The commissioners of public health programmes also have a key role in the management of NGOs contracted, in facilitating the development of management–governance relationships and capacities. This is being increasingly recognized by GHIs, which are now providing support to local

NGOs, to enhance their management and governance capacities (Ravishankar et al. 2009).

Conclusions

Good governance and effective management are critical to the performance of health systems and of public health programmes. Public health programmes vary greatly in size, scope, and coverage, and operate in an environment of changing global landscape and national priorities and systems. Public health governance and management have to be understood as a whole in order to appreciate the rich, dynamic interactions and complexities that characterize it. Systems theory provides a conceptual basis for understanding, studying, and researching health governance as a system and the interactions and relationships within the wider environment of governance in society. Government, the private for-profit sector, and civil society are the institutions of society which make up the three components (subsystems) of the system with distinct structures, institutions, organizations, instruments and tools of influence, and mechanisms and processes for governance. The interactions and interdependencies of the three entities of public health governance are dynamic and evolving. This is evident in global health governance, where roles and influence of the private sector and civil society have gained prominence in the last decade and a half, and new governance forms have emerged such as public–private partnerships and the ‘privatization’ of governance. The principles of public health management and programme management are tools to enhance governance and management of public health organizations. The structure and mechanisms for the governance and management of public health organizations have to be appropriate for their context including considerations such as legal incorporation status, size, complexity, and organizational formality. Governance–management collaboration is critical for organizational effectiveness and complementary roles can be structured to facilitate this. Good governance and effective management ensure that the right things are done right, in the right way.

Implementation science and translational public health

Kedar S. Mate, Theodore Svoronos,
and Dan W. Fitzgerald

Introduction to implementation science and translational public health

As the armamentarium of available technologies and services to improve health and healthcare in low- and middle-income countries grows, there has been a well-recognized gap between the health gains that could be achieved and those that are being realized around the world (World Health Organization 2007). This is not a problem unique to resource-poor countries—some investigators have estimated delays in implementing evidence-based care of up to 17 years in rich countries (Balas-Eltes 2000). Well-known, evidence-based health technologies are not reliably implemented in any context. As the editors of the journal *Implementation Science* wrote in their inaugural issue, ‘Uneven uptake of research findings—and thus inappropriate care—occurs across settings, specialties and countries’ (Eccles and Mittman 2006, p. 1).

In 2001, the Institute of Medicine (IOM) in the United States noted that, ‘between the healthcare we have and the care we could have lies not just a gap, but a chasm’ (Committee on Quality of Health Care in America 2001, p. 1). Scientists and researchers, policymakers, and advocates had concluded that inadequate or incomplete implementation of evidence-based practices in US hospitals had resulted in more than 99,000 avoidable deaths annually. These delays are likely longer and cause more avoidable death and injury in resource-poor settings. Tuberculosis (TB) is an illustrative example: despite knowing the cure for TB for more than 60 years, 1.4 million people died of TB in 2011 (World Health Organization 2012). While the clinical evidence has clearly demonstrated that antiretroviral (ARV) treatment for patients living with TB/HIV co-infection is effective, only 48 per cent of these patients received these life-saving medications in 2011 (World Health Organization 2012).

Implementation science is the study of strategies undertaken to implement evidence-based technologies, services, diagnostics, or therapeutics (referred to henceforth as ‘healthcare interventions’) in ‘real-life’ populations and contexts. The subject of study, as described by the National Institutes of Health (NIH), is the implementation method itself or the ‘strategies to adopt and integrate evidence-based health interventions and change practice patterns within specific settings’ (NIH 2011). The editors of *Implementation*

Science go further in their initial description by suggesting the purpose of this new field of investigation: ‘Implementation research is the scientific study of methods to promote the systematic uptake of research findings and other evidence-based practices into routine practice, and, hence, to improve the quality and effectiveness of health services and care’ (Eccles and Mittman 2006, p. 1). Thus there is an important link between the study of implementation and healthcare quality and effectiveness—a link made by the Institute of Medicine in its *Chasm* report (Committee on Quality of Health Care in America 2001).

The primary aim of implementation science is an optimistic one—focused on finding the opportunities to improve health and healthcare for all populations where gaps in care currently persist. In 2009, the African Academies of Science described one such opportunity when they wrote, ‘If coverage of essential MNCH [maternal, newborn, and child health] interventions reached all families in sub-Saharan Africa and everyone received high quality care, nearly 4 million mothers, newborns, and children could be saved each year’ (African Academies of Sciences 2009, p. 3). The goal of implementation science is not only to inform policymakers that create guidelines and new regulations, but also to examine how and why these guidelines, policies, and regulations too often fail at the front lines of service delivery (Schackman 2010; Padian et al. 2011).

Two examples from the HIV clinical world illustrate the need for implementation science clearly. High rates of preventable HIV infection illustrate gaps in translating research into bedside and community-level results. Preventive health technologies, including ARV medications, can now reduce the risk of perinatally acquired HIV from approximately 25 per cent to less than 2 per cent, and global calls for eliminating perinatal HIV transmission have been issued by the World Health Organization (WHO) and the United Nations (Lindegren et al. 1999; Centers For Disease Control and Prevention 2007; McKenna and Hu 2007; UNAIDS 2011). Yet, despite the promise of these interventions, only 50 per cent of pregnant women are tested for HIV in the highest-burden countries in east and southern Africa, and only 68 per cent of pregnant women living with HIV receive therapy containing ARV medications in these countries (WHO 2010). Failure to deliver well-established prevention of mother-to-child HIV transmission (PMTCT) interventions contributes to the nearly 370,000 babies

Fig. 6.9.1 Number and percentage of HIV-infected people engaged in selected stages of the continuum of HIV care—United States. ART, antiretroviral therapy; HIV, human immunodeficiency virus.

Reproduced from Centers for Disease Control and Prevention (CDC), Vital signs: HIV prevention through care and treatment: United States, *Morbidity and Mortality Weekly Report (MMWR)*, Volume 260, Issue 47, pp. 1618–1623, 2011, available from <http://www.cdc.gov/mmwr/preview/mmwrhtml/mm6047a4.htm>.

infected with HIV each year (United Nations 2000; WHO 2010). Such findings highlight the differences between results obtained in controlled research settings and those recorded in ‘real-life’ health systems with constrained resources and inadequate systems.

Similarly for the clinical management of HIV infection, investigators have described a cascade of interventions from diagnosis to effective treatment that are needed for an HIV-infected individual to improve his or her chances of long-term survival (Fig. 6.9.1) (Centers for Disease Control and Prevention 2011). The points along this cascade represent opportunities for patients to become ‘lost to follow-up’. As the graph clearly shows there are major losses at each step, which represent opportunities for further investigation for implementation scientists.

The purpose of implementation science is to study the myriad approaches to implementation that are taken with any given healthcare technology or service with the goal of understanding how to close gaps between ‘what we know’ (evidence-based interventions) and ‘what we actually do’ at the front lines of healthcare. In the case of each country, the conditions of the context are different—budgets will vary, healthcare personnel will be limited, distribution channels may be fraught, but community assets might be stronger, families more engaged, policies more favourable. Each country and each community will be different, and these differences will in turn affect the implementation approach taken and the consequent evaluation approach. For the purposes of this chapter, we discuss low- and middle-income countries as one block and high-income countries as another block, but we recognize that these groups of dozens of countries and many thousands of communities represent a great deal of heterogeneity that will affect the implementation of any healthcare intervention at the front lines.

Finally, implementation science investigators seek to ensure that the approaches taken to close the gaps described above are based as much on evidence and careful study as the healthcare technologies and services they seek to implement. The audiences

for this evidence on implementation strategies are policymakers, programme managers, health system designers, and global health practitioners. But, most importantly, the audience is the front-line healthcare workers who seek to more rapidly and reliably deliver the fruits of modern medical science to their patients every day.

Locating implementation science

Therapeutic discovery occurs in phases which the NIH has classified as translational steps (Fig. 6.9.2). With each advancing phase the number of clinical subjects that are part of the research study gets larger as confidence in the investigational therapeutic grows. Phase IV trials, included under the ‘translation to practice’ step, are meant to be large-scale studies across multiple heterogeneous practice environments, translating phase III therapeutic efficacy into effective public health programming at scale.

While this image locates implementation science in the third translation, we would argue that the study of implementation is also salient to the fourth translation, ‘to population health’. The order of magnitude is different, but the study of methods and approaches to implementing a healthcare technology or service ‘at scale’ is an important part of the study of implementation. Thus we believe that implementation science ought to span both the third and fourth translations in the conventional research sequence shown in Fig. 6.9.2.

The NIH defines implementation research as a context-sensitive science, explaining that:

Implementation research studies should distance from prior assumptions that empirically-supported interventions can be transferred into any service setting without attention to local context and that a unidirectional flow of information (e.g. publishing a guideline) is sufficient to achieve practice change. Relevant studies should develop a knowledge base about ‘how’ interventions are transported to real-world practice settings, which will likely require more than the dissemination of information about the interventions. (NIH 2012)

Implementation science as a science

Scientific methods and approaches are as vital to the study of implementation successes and failures as they are to the discovery of new diagnostics and therapeutics. Failure to subject the implementation approaches taken to the discipline of scientific testing and analysis will ensure that the current inadequate delivery systems will prevail, leaving the medicines and technologies of modern scientific discovery to reach patients heterogeneously and by chance.

When new evidence-based technologies are introduced, the healthcare delivery system must be adjusted to take advantage of what the new technology can now offer. This adjustment does not happen automatically without deliberate attention to how the health system must change. In fact, as new therapeutic, diagnostic, and preventative technologies are introduced the gap between what is possible and the actual performance of health systems may grow wider (Victora et al. 2000). This 'technology-to-systems gap' means that clinically important discoveries are often held hostage to the inability of our health systems to deliver them. Parallel investment in the study of implementation in health systems will ensure that all patients can reap the benefits of clinically meaningful new technologies.

The tools of today's research community—controlled study designs, randomization, methods to limit bias, and match comparison groups—are perfectly designed to science conducted under the microscope or in clinical research settings. Such tools may not be well suited to study the services provided in hospitals, clinics, or the complex adaptive public health systems in which these organizations operate. However, in resource-limited settings, if we are to create a future that is different from the past with its persistent implementation failures, we will need to apply the rigours of scientific process to a new set of implementation problems. The study of implementation remains foremost a science and requires the discipline of developing new ideas, predicting or hypothesizing their impact, and rigorously assessing the effects of these new ideas in context.

Origins of implementation science

Implementation science shares both quantitative and qualitative analytic traditions as part of its history. W. Edwards Deming's system of profound knowledge lies at the heart of the implementation intellectual tradition (Deming 1993). This system has four central aspects: understanding of systems, understanding of variation, theory of knowledge, and psychology of change. Modern operations research science, industrial process engineering, and the management sciences inform our current understanding of systems. The health systems research agenda, recently articulated at the Global Symposium on Health Systems Research in Beijing, is the best representation of this pursuit of systems thinking. Quantitative studies of practice variation from the 1980s, economic decision analysis, and aspects of industrial quality management form the backbone of understanding variation.

Ethnography, cognitive behavioural sciences, behavioural economics, sociology, and psychology have informed the human factors considerations that are critical to understanding why patients and providers act on certain ideas and reject others. The NIH notes that implementation science fundamentally, 'seeks to understand the behaviour of healthcare professionals and support

staff, healthcare organizations, healthcare consumers and family members, and policymakers in context as key variables in the sustainable adoption, implementation and uptake of evidence-based interventions' (NIH 2012).

Finally, emerging evaluative techniques, including realist and adaptive trial designs, have been slowly reshaping the design of implementation research evaluation. This transformation in how we know what we know forms Deming's final building block on theory of knowledge or epistemology. Implementation science combines quantitative and qualitative analytic traditions into methods that allow learning from the context in which the process of care delivery is actually occurring.

Importantly, implementation science differs from the routine monitoring and evaluation that is common in donor-financed programmes in resource-limited countries. This difference has been most clearly described by Hirschhorn et al. who wrote:

In general, the objectives of monitoring and evaluation programs and implementation are similar: to understand what is working well, what is not working, and why. However, most monitoring and evaluation activities necessarily focus on measuring the services provided rather than on the barriers to implementation. The scientific rigor of implementation research broadens the scope of monitoring and evaluation activities to understand the etiology of gaps between expected results and observed outcomes. (Hirschhorn et al. 2007, p. S528)

Thus despite similarities in objectives and data sources to routine programme monitoring, implementation science remains foremost a rigorous hypothesis-driven investigational activity.

The problems of the new discipline

The study of implementation is complicated by four important problems that are not unique to implementation science, but present particular dilemmas that must be overcome in the design of implementation science studies. These are the problems of scale, context, methods, and overconfidence which are addressed in turn before turning our attention to the details of implementation science study design.

The problem of scale

Current challenges in public health, particularly in resource-poor countries, lie in the effective delivery and scale-up of interventions with proven track records (Victora et al. 2011). A recent study estimated that 63 per cent of the 7.6 million deaths in children under 5 years of age are preventable if just 23 evidence-based preventive and treatment interventions were implemented universally (Jones et al. 2003). Much of maternal and newborn premature mortality is avoidable (African Academies of Sciences 2009). Cost-effective, evidence-based interventions exist to prevent and limit the impact of non-communicable diseases (NCDs) (Beaglehole et al. 2008). The 2007 *Lancet* series on NCDs estimated that if a small subset of these interventions were universally applied in 23 nations, it would save 32 million lives by 2015 (Beaglehole et al. 2007).

The global public health literature is replete with studies of small-scale implementation where a particular problem is addressed using a well-resourced, robust implementation strategy that produces a successful 'pilot' result under study circumstances. This now 'evidence-based' intervention is then appropriately selected by practitioners and policymakers to be

replicated elsewhere. Yet, as the intervention is spread and implemented in multiple different contexts, facing different constraints, and without the carefully controlled study circumstances of the pilot study, the intervention's results are often not replicated.

Take, for example, rapid response systems—clinical interventions designed to provide an earlier bedside response in the hospital setting to a patient's changing haemodynamics and to nursing, patient, or family concerns about changes in the patient's condition (Devita et al. 2006). Several studies in pilot sites found significant impacts of this clinical intervention on inpatient mortality, cardiopulmonary arrest rates, and deaths not in intensive care units (Bristow et al. 2000; Buist et al. 2002). Seizing on these results, numerous organizations sought to actively promote and scale-up the use of rapid response systems, but the pilot testing results could not be replicated reliably elsewhere (Steel and Reynolds 2008).

In a heated exchange in the literature, rapid response teams were criticized severely and the validity of the earlier studies was called into question (Winters et al. 2006). What was overlooked, however, was the fact that the implementation itself—the design of the rapid response teams themselves, the systems in which they were deployed, the culture of the implementing hospitals, and the leadership support (or lack thereof)—was rarely systematically documented, analysed, and interpreted. Without this careful study of the implementation of this complex intervention, a conclusion about the effectiveness of rapid response teams cannot be easily reached.

The problem of context

Scaling up requires a nuanced understanding of how the implementation of efficacious interventions varies across social, economic, and political contexts. It requires an accounting of how these contextual details might exert as much influence on uptake of an intervention as the specific details of the healthcare technology itself (Arifeen et al. 2004).

The problem of context has been well documented by leading epidemiologist John Ioannidis, who studied 45 'evidence-based' medical practices and found that fully a third could not be duplicated in new contexts (Ioannidis 2005). This was illustrated further by Parry et al., 'Simply copying models, without taking account of local context, does not guarantee successful widespread improvement' (Parry et al. 2013). Healthcare technologies found to be effective in a carefully designed trial may not be as effective in contexts that are dissimilar to the one in which they were initially studied. Indeed, as the implementation context varies further from the context of the original efficacy study, the chances of implementation success may diminish further. Efforts to study, measure, and understand the role of context and its influence on implementation are underway (Kaplan et al. 2010; Svoronos and Mate 2011).

In addition to the social, economic, and political contexts in which healthcare interventions are deployed, one must also consider that healthcare organizations are themselves constantly changing which may influence the uptake of an intervention. In order to better inform service delivery, ongoing evaluations of implementation effectiveness will need to provide implementers with real-time continuous feedback on how they are changing to affect outcomes (Rowe 2009; Victora et al. 2011). Summative evaluations that spend years collecting baseline data and reporting on results after the conclusion of the intervention are no longer adequate. Going back

to the example provide earlier, one commentator noted, 'An RRS (rapid response system) is not a drug treatment, a hospital is not a body. Both are continually changing, complex social interventions' (Øvretveit and Suffoletto 2007).

The problem of method

Despite some understanding of these needs, the techniques and methods for studying implementation across contexts and at scale remain underdeveloped and underreported in the literature (Victora et al. 2004, 2011). Instead, study designs built to evaluate the efficacy of a clinical intervention in a controlled setting or to study a biomedical compound in the laboratory are often mistakenly applied to study and interpret the effectiveness of both the intervention and the implementation approach (Oxman et al. 1995; Øvretveit and Gustafson 2003). These designs, including the fixed-protocol randomized controlled trial, are primarily capable of assessing an intervention in controlled situations that rarely imitate 'real life'.

Methods for studying the variety of approaches that may be taken to implement a new diagnostic technique or therapeutic across heterogeneous contexts remains scarcely documented. The journal *Implementation Science* was introduced only in 2006 and it remains the only journal dedicated to advancing the methodology of studying implementation. The journal, 'aims to publish research relevant to the scientific study of methods to promote the uptake of research findings into routine healthcare in clinical, organizational or policy contexts' (*Implementation Science* 2014). Such approaches are welcome, but need to be expanded and further developed. Additionally, although *Implementation Science* encourages contributions from developing countries, only a small fraction of the studies appearing in the journal describe implementation studies from resource-limited contexts.

The problem of overconfidence and unintended variation

Finally, despite multiple documented failures of implementation of evidence-based technologies in high- and low-income settings, we continue to place undue faith in our clinical practitioners—insisting that when confronted with the evidence and mounting guidelines, they will make the right decisions and will deliver all necessary care to everyone in a timely and reliable manner. The principles of authority, autonomy, and independent responsibility for services to the individual patient are deeply embedded in the psychology of the practitioner and in the psychology of many patients who seek the expert counsel of their doctors (Berwick 2009).

This compact between patient and doctor is in many ways the foundations of the profession, but variations in clinical practice for even common conditions like pneumonia, heart failure, and myocardial infarction are now a well-documented phenomenon (Wennberg 1998; Fisher et al. 2009). Physician decisions are influenced by their peers, by their patients, and by their professional societies. Reliable implementation is destabilized by these external forces which must be measured in order to be successfully brought under control. The sobering data describing enormous practice variation for even the most basic of evidence-based practices serves as a persistent reminder not of the failure of intention on the part of physicians, but failures of systems design to support practitioners to make the right thing to do, the default thing to do.

Implementation science study design

We review the core elements of study design including: understanding the subject of study, identifying the primary research question, planning measures, and selecting the format for the study including considerations of control groups and strategies for eliminating bias. These are not unique to implementation science studies, but in the context of studying implementation they do have unique features.

Understanding the subject of implementation science: the approach to implementation

Before proceeding further it is worth describing the subject of study further. Implementation science focuses upon the approaches used to implement a healthcare technology, service, diagnostic, or therapeutic. The units of study may be individual patients, but more often the units of study are health facilities, hospital wards, health districts, or geographic populations where different approaches are used to provide a healthcare technology. As a clinical researcher studies new interventions and tries to characterize and control for the variability between individual patients, the implementation scientist studies new approaches to provide an existing technology and tries to characterize and control for variability between units of study (health facilities, hospital wards, health districts, etc.).

The implementation scientist may or may not be involved in the implementation effort itself. While it may be cleaner to have the implementation effort be conducted by one group and the study of the implementation approach done separately by an unbiased individual or organization, there are often many situations in which this separation is unrealistic and impossible, especially in resource-constrained settings.

There are many approaches to implementation of a healthcare technology, service, diagnostic, or therapeutic. The healthcare intervention itself is not under study (e.g. antibiotic, diagnostic test, procedure)—these are studied elsewhere using conventional biomedical and clinical research tools described in great detail in textbooks of clinical research methods. Implementation science is the study of the approaches taken to reliably providing these technologies across heterogeneous contexts. A non-exhaustive list of examples of implementation approaches might include:

1. Executive mandate—the quintessential top-down approach where a chief executive requires, or mandates, a group of individuals, an organization, or a geopolitical entity to implement a healthcare intervention.
2. Guidelines—also known as ‘clinical practice guidelines’, these are practice recommendations developed by a discipline’s governing academic society or group of expert practitioners. Guidelines are often amalgamated from the clinical trials results and are thus referred to as being ‘evidence based’.
3. Clinical protocols or pathways—based on clinical practice guidelines and standards, but locally adapted, these protocols or pathways are the literal step-by-step translation of the guidelines to help local practitioners provide guideline-based care to their patients. Protocols or pathways often are represented as flow charts, algorithms, or other similar diagrams.

4. Training—an important implementation approach that focuses primarily in providing knowledge to clinicians, healthcare workers, patients, and families. There are many more specific approaches to training including train-the-trainer approaches, on-the-job training (hands-on), variations based on who the trainer and trainee are, and many variations of how the training is delivered (e.g. didactic, workshop, online, in-person, team-based, etc.).
5. Task shifting—often the approach to improvement may involve changing the types of personnel or locale where a health technology is provided. For example, vaccines may be more efficiently distributed to a population in pharmacies than in physicians’ offices.
6. Checklists—a tool which provides a simplified visual reminder of aspects of a clinical protocol or pathway. Checklists are designed to improve consistency and reliability of implementation (Haynes et al. 2011).
7. Campaigns—similar to political campaigns, public health campaigns have been used to spread evidence-based clinical practices to a large region. Historically used in low-resource settings to improve delivery of vaccines, ARV medications for HIV (the WHO’s ‘3 by 5’ Initiative), and simple surgical procedures (male medical circumcision, cataract surgery). More recently campaigns have been used in the United States and Europe to improve patient safety and reduce hospital-acquired infections (Berwick et al. 2006; McCannon et al. 2007b; Motsoaledi 2010).
8. Laws and regulation—similar to executive mandate, legal and regulatory mechanisms work to enforce implementation of healthcare practices. National governments can legislate the right to basic primary healthcare services for their citizens as a primary method for implementation.
9. Pay-for-performance and use of incentives and penalties—incentives or disincentives for implementing a procedure or conducting a service is a hotly debated approach to improving implementation consistency and reliability. ‘Payment’ can come in many forms including financial, public recognition, or other forms of penalty or reward (less frequent licensure visits, faster reimbursement, etc.).
10. Process improvement—derived from management sciences, this approach views dynamic healthcare systems as complex processes which can be systematically improved using a combination of tools to diagnose system failures (e.g. process maps), an incremental problem-solving approach (e.g. Plan–Do–Study–Act cycles), and time-series measurement and evaluation techniques. (See Box 6.9.1 for more detail.)

This is far from an exhaustive list, but it gives the reader an impression of the heterogeneity of approaches that are taken to improve implementation. These approaches, alone or in combination, along with myriad variations, are the focus of study in implementation science. Further, the reader can begin to understand the complexity of characterizing and controlling for the variability between units of study which are often large organizations or populations.

Box 6.9.1 The quality improvement approach

The quality improvement (QI) approach is an implementation method that is grounded in operations research and management science, two well-established fields that have combined the disciplines of statistics, psychology, systems engineering, and iterative learning, to have major impacts on systems performance across countries and industries. QI seeks to design systems for maximum effectiveness, efficiency, and adaptability and to actively disseminate the best models for health service delivery at a rapid rate. Specialized, evidence-based tools aimed at rapid-cycle iterative testing of changes, networked collaborative learning, development of institutional capability for continuous improvement, and frameworks to guide large-scale change have been developed to facilitate this process. The QI approach supports a shift in provider attitudes and practice from a prescriptive mode to one that supports critical thinking and problem-solving skills with continuous review and improvement of service provision.

Healthcare quality improvement principles and the model for improvement (Fig. 6.9.3) provide an effective approach to help close implementation gaps. The approach places a premium on data-driven front-line decision-making, peer-to-peer knowledge exchange, local adaptation of clinical protocols, and highly participative management. Originally developed in the United States and widely adopted in the United Kingdom and other high-income nations, these efforts have increasingly found their way into global health applications in low- and middle-income countries.

Application of the QI approach to health systems of low- and middle-income countries shows considerable promise. Efforts in the Russian Federation have reduced neonatal mortality by 60 per cent (Quality Assurance Project 2001); in Niger, malnutrition-related fatality was halved in a single year (Catsambas et al. 2008); in Ecuador, an essential obstetric care collaborative substantially reduced the incidence of postpartum haemorrhage (Hermida et al. 2005); in projects in South Africa, rapid scale-up of access to HIV care and treatment services and falling rates of mother-to-child transmission of HIV at a district level have been demonstrated (Barker et al. 2007; Doherty et al. 2009).

Traditionally this approach is used following policy formulation and where some programme implementation experience has already been established. This often means that healthcare providers have to unlearn what they have been doing for years and replace with new enabling and empowering approaches that involve critical thinking and problem-solving skills, which have the added advantage of application to other health challenges facing the facility or service.

Identifying the primary research question

As already described, the focus of an implementation science study is on *whether* a particular approach to implementing a healthcare technology or service is successful or *why* it has succeeded or failed. Researchers may investigate *what* combinations of approaches work best or what sequence is optimal, *who* should provide a service, or *where* a service is best delivered. Alternatively, researchers may explore why the same approach succeeds in one context but fails in another.

An analysis, both qualitative and quantitative, of the barriers and challenges to implementation may make up the formative research that is needed to decide on what particular approach would be most successful to implement a healthcare technology or service in a specific context. In addition, a local contextual analysis may help guide implementers to the likely adaptations to a healthcare intervention that will be needed to improve its local implementation.

Implementation scientists can also guide the implementers to sequence their effort in a way that allows for more effective study of the implementation approach. As an example, in Andhra Pradesh, India, a newly legislated health insurance system for high-cost surgical procedures for the poor was rolled out in stages throughout the 23 districts in the state which allowed investigators to exploit differences in rollout times to study the impacts of the system on the intended beneficiaries (Fan et al. 2012).

Planning measures

The measurement framework for an implementation science study will be a composite of input, process, outcome, and impact measures.

Input measures will measure whether the specific components of the implementation approach are delivered to the organization or population as needed. For example, in a study of a process improvement implementation approach for delivering syphilis

testing and treatment to pregnant women in Haiti, the number of basic trainings on process improvement for the participating sites and monthly follow-ups were reported (Severe et al. 2013). Similarly, inputs to a guideline- and training-based implementation approach to improving childhood survival, the Integrated Management of Childhood Illness, was described in Ghana, Benin, and Mali (Bryce et al. 2010).

Process measures seek to break down the implementation process itself into its component parts to understand whether they are carried out with fidelity. For example, in the syphilis testing and treatment implementation study just described, process measures would seek to understand at each of the participating sites whether specific processes related to the implementation approach were being carried out: in this case, whether process mapping had been conducted, whether facility-based process improvement teams were meeting on a regular basis to problem-solve, and whether data on syphilis testing and treatment rates was being tracked over time.

Outcome measures in the case of implementation science will focus on whether the implementation approach succeeded in delivering the healthcare technology or service to the intended target population. For example, in the process improvement example described earlier, the programme focused on whether pregnant women were being tested for syphilis and for those requiring penicillin treatment whether they were receiving the needed medication.

Impact measures follows whether the healthcare technology or service produces the patient-level results that it is designed to produce. The gold standard for impact assessment are the results produced by healthcare technologies and services under tightly controlled randomized controlled trial circumstances. In the example of syphilis testing and treatment, impact measures would include an assessment of the overall rates of congenital syphilis in the clinic's catchment areas and a comparison to the rates that might have been achieved in the original controlled efficacy studies of penicillin for prevention of congenital syphilis.

Selecting a study format

The gold standard of study design is the randomized controlled trial. In implementation science, 'cluster' randomization is often used as the units of study are villages or health facilities where different approaches to provide a service are tested. A fixed-protocol randomized-controlled trial design reduces bias, limits contamination and confounders, and tests a single hypothesis. Unfortunately, while it is the gold standard, randomized trials are often not feasible or practical in the conduct of implementation science. They are large, costly, and conducted over long periods of time with significant delay between initial study conceptualization and realization of results (Berwick 2007). Therefore, a number of other study approaches have been developed. These are briefly described as follows.

Several authors have proposed alternative methodologies to evaluate large-scale interventions and implementation approaches. Pawson and Tilley's 'realistic evaluation' method proposes a framework that is best summarized by the equation 'context + mechanism = outcome' (Pawson and Tilley 1997). Briefly, this framework suggests that the impact ('outcome') of an intervention is the product of the pathway through which an intervention produces change (its 'mechanism') and how that pathway interacts with the target organization's existing reality ('context').

Realist evaluations embrace the notion that all studies are driven by an implicit theory about the implementation approach that is needed to drive improvements in healthcare outcomes in a population. It uses techniques to make these 'implementation theories' explicit by identifying them and subjecting them to hypothesis testing. In order to do this, the evaluation must capture not only data about the impact of the healthcare intervention on the population, but also data on the fidelity of the specific implementation approach to prove or disprove the implementation theory. By analogy to clinical studies, researchers must show the 'adherence' to the implementation approach under study.

Alternative evaluation frameworks have been proposed as a way of shortening delays between study concept and result with the idea of capturing data in real time to aid and nuance the implementation approach that is being tested. The integrated continuous survey methodology proposed by Rowe et al. suggests a regular data review of key systems performance and implementation indicators that are closely tied to decision-making at the local level. Focused audit studies generally involve periodically assessing the progress of the implementation of an intervention by monitoring key variables over time. Multiple case studies take the opposite approach, randomly choosing several successful recipients of an intervention and studying the implementation approaches used in each case in detail (Harvey and Wensing 2003). Process evaluations involve studying the implementation approaches for the primary purpose of understanding if each stage of implementation was successful (Oakley et al. 2006). Examples of process evaluations include programme impact pathways and results chain evaluations (Victora et al. 2004).

Alongside these methodologies, 'theory-based evaluation' has been proposed to further understand the details of the actual process of change that an intervention seeks to produce, rather than relying exclusively on quantitative data before and after the intervention. For example, evaluating a behaviour change programme must involve specifying how particular components (mass media advertisements, information sessions, etc.) will lead to the desired changes in population behaviour. Such evaluations typically rely on qualitative study designs and require that any quantitative data that is captured be interpreted through the lens that this qualitative data is used to produce.

Finally, in order to capture the subtleties of why a particular implementation approach succeeds or fails in a given healthcare context, implementation scientists often used qualitative techniques. These techniques allow for the development and refinement of explanatory theories for implementation success or failure. Ethnographic and system documentation tools, like the driver diagram, can be used to facilitate this process (Svoronos and Mate 2011).

Control groups

As with clinical research, the study of implementation approaches faces questions about how to limit or reduce bias and how to establish adequate counterfactuals and control groups that would provide appropriate comparisons. With clinical research studies, randomization is often regarded as the predominant tool to reduce or eliminate bias—in this case by spreading confounders evenly throughout the intervention and control arms of the study.

With implementation science, often randomization is neither possible nor practical and may have a diminished impact on reducing bias. In a detailed examination of this issue, English et al. describe several problems with randomization in implementation studies. In sum these include:

- ◆ **Number:** with increasing size, fewer and fewer health units are available for randomization.
- ◆ **Balancing confounders:** with fewer and more complex health units, the ability to balance confounders between control and intervention arm may not be possible.
- ◆ **Complexity:** with increasingly complicated multistep implementation interventions, the opportunities for bias and confounding at each step become legion and it may not be possible to account for this complexity in the randomization. In particular, it may be difficult to account for this complexity a priori before the implementation study is underway and the contextual complexity becomes apparent.
- ◆ **Contamination:** in complex, real-life scenarios, health units randomized to the control arm may be shifted towards the intervention by geopolitical forces beyond the control of the investigators.

The point here is not to dismiss or devalue randomization—it is an important and effective tool for trying to reduce bias. However, one should not overestimate the effects of randomization, particularly

in the study of implementation approaches where the power of randomization alone to reduce bias may be limited.

A number of other strategies have been developed to establish control groups. We outline these in Table 6.9.1. In lieu of starting out with a priori controls, quasi-experimental designs add and subtract factors considered to affect outcomes sequentially over time (Rogers 2000; Victora et al. 2004; Walshe 2007). Stepped wedge designs where the intervention is rolled out in stages to increasing numbers of health units are particularly useful approaches (Hussey and Hughes 2007). In these stepped wedge designs, a number of health units are divided into groups or ‘steps’ ahead of time and the intervention is sequentially introduced to each step at predetermined points in time. The health units that have received the intervention are in the intervention arm and those in the ‘steps’ that await intervention form a natural concurrent control group. Over time with each ‘step’, the intervention group expands to include additional health units and the control arm decreases in size.

Where concurrent controls are not possible (e.g. in a large-scale nationwide campaign to provide vaccines to children), historical comparisons will be needed to detect whether implementation approaches are demonstrating improved health system performance and outcomes. Continuous or interrupted time series studies, and segmented regression analysis can be used in these circumstances to provide the statistical support needed (Finison and Finison 1996; Wagner et al. 2002; Thor et al. 2007).

Table 6.9.1 Study design and control groups in implementation science

Study design	Description of control group	Strengths and weaknesses
Randomized controlled trial	This is the gold standard method to limit bias and confounders. Health units are randomized to receive the experimental implementation approach(es) or not. The groups are then compared after time	There may not be sufficient numbers of health units to randomize or the large number required makes the trial impractical. There may be contamination across randomization group. The size of these trials makes them expensive and lengthy
Stepped wedge	A number of health units are divided into groups or ‘steps’ and the intervention under study is sequentially introduced to each step at predetermined points in time. Units that have not yet received the intervention serve as controls	There may be contamination across groups as ‘step’ groups learn about the new approach and implement it before the predetermined time. Concurrent changes in context over time, unrelated to the study, may impact study outcome and confound results
Time series (continuous, sequential, interrupted)	Health units serve as their own controls as interventions are introduced continuously, sequentially, or in discrete interrupted pattern. Feedback may permit further adjustment and improvement of approach	While improvement can be measured and established, asserting causality between the individual interventions and the improvement is difficult
Case–control	Health units (facilities, wards, villages) that have successfully implemented change are compared to health units that have not. Researchers compare implementation approach or context characteristics of successful versus unsuccessful health units. Simple and fast study design	This design can be used to generate associations and hypothesis but given the complexity of implementation approaches and characteristics of health units, there are numerous potential confounders
Historical control	A comparison of outcomes in a group of health units before and after an intervention has been introduced	Subject to implementation ‘placebo’ effect. Health units tend to do better when someone is watching regardless of the intervention under study. Concurrent changes in context over time, unrelated to the study, may impact study outcome and confound results

In addition, such designs and analytic techniques can provide the type of constant feedback needed for implementation activities to be further adjusted and improved within prevailing contextual circumstances (Nelson et al. 2004; Speroff and O'Connor 2004).

The optimal evaluation of an implementation approach will be a mixed methods approach drawing on the quantitative techniques described above to examine whether the implementation approach under study is succeeding or not, along with qualitative techniques that will provide the context-specific detail to explain how and why the implementation approach produced the result that it did.

Review of implementation science in low- and middle-income countries

Implementation science studies from low- and middle-income countries have been reported in the literature since the late 1990s, initially focused on strengthening health promotion and changing healthcare provider behaviours. The literature on implementation research was dramatically accelerated by the launch of the journal *Implementation Science* in 2006. However, reports from low- and middle-income countries became more prevalent after 2008 when the US government's President's Emergency Plan For AIDS Relief (PEPFAR) made implementation research a core part of its strategy (Padian et al. 2011). In addition, the literature expanded as countries worked to implement evidence-based practices to achieve the Millennium Development Goals. Implementation science studies from low- and middle-income countries are thus particularly strong in three dimensions: HIV, maternal and child health, and health systems strengthening.

HIV

Implementation research has been used to study HIV prevention including methods to prevent mother-to-child HIV transmission (De Cock et al. 2000), improve uptake of male medical circumcision (Kebaabetswe et al. 2003), and reduce HIV risk from drug use through needle exchange syringe distribution, ARV treatment programmes for active drug users, and opioid substitution therapy (Wood et al. 2008).

ARV treatment programmes for HIV have also been the subject of implementation science studies. Once run through central urban tertiary care centres, HIV programmes throughout the world are now being decentralized to ensure wider and more equitable access to ARVs. However, shortages of trained healthcare workers and challenges of integrating HIV/AIDS care into routine primary healthcare remain barriers to reliable provision of ARVs. Implementation studies have evaluated clinical guideline adaptation and training, such as the PALSA PLUS programme in South Africa and the PALM PLUS programme in Malawi (Schull et al. 2011). These studies suggest that despite variations in health systems, the principal obstacles to decentralization can be overcome by a combination of improving healthcare worker retention and satisfaction while improving the quality of care.

In addition, HIV treatment expansion efforts require new personnel to prescribe and deliver life-saving ARVs. Implementation science studies have helped to demonstrate that nurse-initiated and -managed antiretroviral treatment (NIMART) is both feasible and acceptable in the South African health service (Cameron et al. 2012). Formative implementation research into NIMART

described workload and capacity constraints, the logistical and infrastructural challenges faced, the training and support needed, and the new working and referral relationships between health staff that would be needed. These formative results optimized the intervention design and allowed a more nuanced selection of implementation approaches including a combination of clinical guidelines tailored to nurses, and significant health services reorganization (George et al. 2012).

PEPFAR has welcomed implementation science and the US Agency for International Development has twice released programme statements seeking implementation science proposals to improve HIV service delivery in low- and middle-income country settings. The HIV research community has welcomed the advent of this field, signified by the launch of a new section on 'Implementation and Operational Research' in 2010 in the *Journal of Acquired Immunodeficiency Syndrome*. However, in order for implementation science to gain further ground, there will need to be better coordination and integration of the findings from this research and the programme delivery efforts themselves (Norton et al. 2009; Schackman 2010).

Maternal and child health

A second area of focus for implementation scientists in low- and middle-income countries is efforts to improve the delivery of care for mothers and children. Several implementation approaches have been tested in varying contexts. First, promotion of clinical practice guidelines has met with varied results in Burkina Faso, Ghana, and Tanzania (Baker et al. 2012). WHO's Integrated Management of Childhood Illness, which combines evidence-based care protocols with a train-the-trainer programme, has been studied carefully by implementation scientists seeking to understand what contextual and programmatic factors have led to implementation success and failure (Bryce et al. 2010). Efforts by Spector and Gawande to develop a safe childbirth checklist build on successful applications of checklist reminder systems in other contexts (operating room care, critical care, etc.) (Spector et al. 2012).

Kangaroo mother care (KMC) is a safe, cost-effective method of caring for low-birth weight infants and improving newborn survival rates. *KMC Ghana*, an initiative to scale up KMC in four regions in Ghana, utilized two implementation approaches: (1) train healthcare facilities that conduct deliveries with the necessary skills for KMC practice and (2) use validated KMC-specific data collection tools to monitor progress and provide facility-level feedback (Bergh et al. 2012). In Ecuador, the Quality Assurance Project (QAP) and the USAID Health Care Improvement Project (HCI) assisted in the adoption, scaling up, and institutionalization of active management of the third stage of labour (AMTSL) for prevention of postpartum haemorrhage via a continuous quality improvement implementation approach. This approach used techniques adopted from industrial process engineering to improve patient flow, streamline care delivery processes, and remove operational barriers (Hermida et al. 2012).

Various implementation approaches have been taken to improve the delivery and uptake of evidence-based vaccinations. Mass-immunization campaigns have been used in a number of settings, particularly with the recent efforts to eradicate polio infection (Institute for International Programs, 2008a, 2008b, 2008c). A number of strategies have been used to improve

communication to parents and children about the benefits of vaccination. To organize these efforts and to study their effects on childhood immunization rates, the Communicate to Vaccinate (COMMVAC) project has been established. This project studies communication strategies aimed at improving communication with parents about vaccines (Lewin et al. 2011). Child health programmes have used campaigns in a variety of other contexts as well as to deliver key health interventions on a broad range of topics such as breastfeeding promotion (Bosnjak et al. 2004), insecticide-treated nets (Institute for International Programs 2008a, 2008b, 2008c), and interventions to prevent congenital syphilis (Saraceni and Leal 2003).

Financial incentives have been well studied by implementation scientists for their potential impacts on the implementation of evidence-based care for mothers and children. Several studies examined the impact of financial or other material incentives provided to mothers and families upon achievement of certain caregiving behaviour such as vaccination (Institute for International Programs 2008c), in-facility delivery (Chiwuzie et al. 1997; Bhat et al. 2007; Lim et al. 2010), antenatal and/or postnatal visits (Mushi et al. 2003; Morris et al. 2004; Bhat et al. 2007; Moloney, 2010), and education attainment (Morris et al. 2004; Fernald et al. 2008). In India, a government-sponsored conditional cash transfer was associated with fewer perinatal deaths (Lim et al. 2010). But not all financial incentives seem to work. In the Accelerated Child Survival and Development programme in Mali, incentives to improve childhood vaccination did not improve child survival in intervention versus control areas (Institute for International Programs 2008c).

Health systems strengthening

Interest in strengthening health systems has led to renewed interest in studying implementation efforts that would also lead to stronger health systems (WHO 2007). While the majority of this literature is also related to HIV and maternal and child health implementation studies, two types of studies deserve specific mention. The first are efforts to study the translation of evidence-based research into policy. While the focus of implementation science is on the study of the uptake of research findings into clinical practice, a growing body of evidence is beginning to describe the challenges in translating evidence-based findings into policy (El-Jardali et al. 2012; Lavis et al. 2012; Lewin et al. 2012). Solutions are emerging as well, including dynamic new social networks such as the EVIPNet, sponsored by the WHO, to improve collaboration between researchers and policymakers (Lavis and Panisset 2010).

Finally, implementation scientists have been determined to approach implementation at scale. Strategies for taking a health-care intervention to scale—whether through the mass media, social networks or the use of technology, or more conventional approaches to community organizing, facility-level investment, health camps, or campaigns—are now under scientific scrutiny thanks to the efforts of implementation scientists (McCannon et al. 2007a). Importantly, implementation scientists seek to understand both whether the scale-up approach was successful and why it succeeded. This tacit knowledge, often poorly documented, includes a practical understanding of the settings and the contexts in which the intervention was scaled up and may lead to improved implementation and scale-up in the future (Massoud et al. 2012).

A review of implementation science in high-income countries

Implementation science has found an increasingly prominent role in health services research in high-income countries. Given the wide variation in both the cost and quality of health services in the United States, there is considerable interest in understanding how evidence-based guidelines can be translated into effective care. Support for such initiatives has come from governmental agencies (Agency for Health Care Research and Quality), health providers (Kaiser Permanente), academic journals (*British Medical Journal Quality and Safety*), and insurers (Blue Cross) among others (Rubenstein and Pugh 2006). Though still a nascent discipline, implementation research has facilitated several successful health interventions on a large scale. For example, Lorig et al. (2001) found significant gains from a chronic disease self-management training programme, primarily focusing on the diffusion of best practices for self-care among arthritis patients. The success of this intervention, studied both as a randomized trial and using quasi-experimental methods, has led to its widespread implementation across the United Kingdom. A comparable programme focused on diabetes prevention through community health workers also achieved significant improvement in both glucose levels and weight (Katula et al. 2011). Again, the initial success of this programme was supplemented with multiple study replications in various settings. These replications were largely able to mimic the findings of the initial efficacy trial. Perhaps more importantly, they provided insights as to how this intervention could best be adapted to various community settings and with varying levels of resources (Glasgow et al. 2012).

The US Veterans Affairs Quality Enhancement Research Initiative (QUERI) is particularly useful in revealing the various strengths of implementation research. This programme was created to address the gap between evidence and clinical practice in health service provision within the Veterans Health Administration, with an emphasis on quality improvement (Stetler et al. 2008b). QUERI was the focus of a series of articles published in *Implementation Science*, ranging from theoretical frameworks to empirical studies. For example, Stetler et al. (2008a) presented the organizational framework underlying QUERI, which focused on cultural norms, resource capacity, and supportive infrastructures as the three contextual determinants of implementation success. These principles were used in the rollout of programmes aimed at reducing HIV risk (Goetz et al. 2008), treating schizophrenia (Brown et al. 2008), and improving eye care for diabetic patients (Krein et al. 2008).

Despite these notable examples of implementation science in practice in high-income settings, disagreements persist in the terminology and theoretical frameworks underlying implementation science. For example, a 2009 article identified over 30 distinct definitions of dissemination and implementation, and questioned whether the discipline could progress before reconciling them (Proctor et al. 2009). Many have emphasized the need for unifying theoretical models as a way to unify these definitions (Rubenstein and Pugh 2006), while others have emphasized the distinctive methodological needs of the discipline (Wallace and Legro 2008; Mdege et al. 2011). The Cochrane Effective Practice and Organization of Care (EPoC) Group, a review group of the Cochrane Collaboration, has the potential to resolve these

differences. By taking a meta-analytic approach to interventions focused on improving the delivery of healthcare services, EPOC is well placed to find unifying trends in the implementation science literature.

Conclusion

The study of approaches to implementing care at the bedside and in the community is a field in rapid evolution. The discipline is new and the approaches and methods used are under active development. At the moment, despite the availability of useful alternatives, conventional approaches to study design and analysis, designed for clinical research trials, are often applied to the study of implementation approaches.

Implementation science requires a deep understanding of health systems, of variation in behaviours and outcomes over time, of psychology of patients and practitioners, and of the way knowledge is developed and spread. It seeks to understand the complexities of how and why healthcare delivery succeeds and fails at the bedside and in our communities.

Environmental health issues in public health

Chien-Jen Chen

Environment and health: historical perspective

Human beings live in a complex environment. The importance of environmental factors in human health has been recognized since antiquity. Hippocrates, in his classical writing *On Airs, Waters and Places*, emphasized the relevance of the environment to human health (Hippocrates 1950). He pointed out the influence of seasons and weather, location of residence, and nature of water on human health, and the occurrence of *epidemics*. Since ancient times, the seasonality of infectious diseases and the geographical clustering of endemic diseases have been documented worldwide. Several hypotheses had been advanced to explain the unique distribution of various diseases in time and place. The contagion theory proposed that both direct and indirect contact with sick people or animals might transmit diseases and hence both isolation and quarantine had been suggested to prevent the spread of diseases. Although they might have reduced the risk of spread of infectious diseases by ships, the strategies evolved from the contagion theory had not stopped the outbreak of many infectious diseases.

The miasma theory proposed that dirty living environments, unclean drinking water, and poor ventilation due to overcrowding might cause various diseases (Hamlin 1998). This led to environmental sanitary reforms aimed at removing miasma by contributing to a cleaner environment in Europe. The hygienic movement emphasized the importance of implementing a safe drinking water supply and sewage disposal system. The Public Health Act enacted in Britain in 1848 was considered the first example of governmental involvement in public health affairs. However, a large outbreak of cholera still occurred in London despite its well-constructed sewage disposal system and much improved environmental sanitation in the 1850s. Through a carefully designed survey, John Snow published his famous epidemiological study on cholera in 1855 (Snow 1936) while the germ theory was still in its infancy. He identified the consumption of contaminated drinking water as the cause of the cholera outbreak. The removal of the handle which pumped contaminated water ‘magically’ prevented the spread of the disease. The relocation of sources of drinking water successfully controlled the cholera outbreak. This was a pioneering epidemiological study in the identification of environmental factors in a disease outbreak.

In late nineteenth century, the development of germ theory led to the discovery of many specific infectious agents for human diseases. It also led to the development of several drugs for treatment of diseases, and improvements in sanitation and disinfection to

control outbreaks of diseases. Koch’s postulates (Koch 1891), which emphasized a one-to-one relationship between cause and disease, were well accepted as criteria for the identification of causal agents of infectious diseases. Effective control of several infectious diseases through identification of specific agents, discovery of chemical and biological drugs, and invention of preventive and therapeutic vaccines had improved life quality and longevity of human beings. The discovery of animal reservoirs and vectors of infectious agents led to the control of vectors through environmental sanitation and disinfection. More and more biological and mechanical vectors have been identified for various viral, bacterial, and parasitic diseases since then. Control of vectors in the environment using pesticides became an important task for the prevention of infectious diseases. For example, malaria was eradicated in Taiwan through the detection and treatment of infected cases and use of the insecticide DDT. However, the widely used pesticides polluted the environment and became hazardous to wild animals and humans.

Life expectancy in most countries increased significantly after the 1950s, when conventional infectious diseases had been controlled through the widespread use of various vaccines and antibiotics. The major diseases that threaten human life have since gradually shifted from infectious to chronic non-communicable diseases. Environmental factors with exposures through lifestyle habits, dietary intakes, and environmental pollution play important roles in the development of chronic diseases such as cancers, cardiovascular diseases, and neurological disorders. There are multiple risk factors in the complex pathogenesis of chronic diseases. For examples, risk factors for ischaemic heart disease included hypertension, diabetes, hyperlipidaemia, cigarette smoking, obesity, lack of exercise, and environmental pollutants. Some environmental pollutants may cause several chronic diseases in multiple organ systems. For example, arsenic in drinking water has been documented to induce cancers of the skin, bladder, kidney, and lung, blackfoot disease, ischaemic heart disease, stroke, hypertension, diabetes, erectile dysfunction, mental retardation, neurological disorder, cataract, and pterygium. The classical Koch’s postulates for judging the cause of disease are less applicable to chronic diseases. Hill’s criteria including the strength, dose–response relation, temporality, specificity, and biological plausibility of the association between risk factor and disease have been widely adopted for the identification of causes of various diseases (Hill 1953).

Endemic diseases are often characterized by their unique geographical clustering. This clustering may be associated with biological or chemical agents prevailing in local environments. Some

parasitic diseases such as schistosomiasis remain endemic in areas where the ecological system maintains the life cycle of the parasites. The interruption of the life cycle through the identification and treatment of affected patients, eradication of vectors, and improvement of environmental sanitation may decrease the prevalence of these endemic parasitic diseases. Some endemic diseases such as goitre and blackfoot disease are caused by the deficient or excessive intake of certain chemicals in the environment. High concentration of fluoride and arsenic in well water has been identified as the cause of fluorosis and blackfoot disease, respectively. The replacement of well water with surface water with low concentration of these chemicals had decreased the occurrence of the associated diseases. In the case of endemic goitre caused by low dietary intake of iodine, salt iodization has been implemented to effectively prevent it.

There has been a long-standing recognition that the workplace environment can induce occupational diseases. Ramazzini published his seminal treatise on diseases of workers (Raffle et al. 1987). Scrotum cancer had long been considered a disease of chimney sweeps. The poor working environment in the nineteenth century sparked reform attempts in Europe, but specific regulations to protect workers against occupational diseases were mostly implemented in the twentieth century. Occupational hazards may spread from the workplace to its adjacent environments. For example, a major gas and chemical leak incident in a pesticide plant in Bhopal, India in 1984, and the 1986 accident at the Chernobyl nuclear power plant in Ukraine resulted in environmental disasters. In addition to the immediate casualties, both events also increased the risk of a number of chronic diseases in residents living in the vicinity. The health hazards induced by long-term exposure to industrial wastes are usually more insidious than those resulting from acute environmental disasters. Environmental pollution by industrial waste has been well documented to cause Itai-itai disease and Minamata disease in Japan. Chronic poisoning by heavy metals in industrial waste has become an important issue in environmental health. Soil and water contamination by widely used agricultural chemicals have brought significant threats to human health, wild animal life, and ecological sustainability. Air pollution has increased the risk of pulmonary diseases including asthma and chronic bronchitis, as well as ischaemic heart disease.

Natural disasters including snow-storms, hurricanes, floods, sand-storms, and forest fires have had serious consequences for public health. Other environmental disasters including earthquakes, tsunamis, and landslides are also detrimental to human health. The explosions that occurred at the Fukushima nuclear power plants in the aftermath of the major earthquake and tsunami in Fukuoka, Japan in 2011, resulted in a multiple environmental disaster. In addition to the heavy immediate casualties, natural environmental disasters threaten the function and efficiency of food, water and electricity supply systems, ambulance and health care systems, sewage and waste disposal, and the control of infectious diseases. Protecting public health through proper environmental management is becoming a lasting challenge.

Causes of human diseases: host-agent interaction in the environment

Both host and environmental factors are involved in the development of human diseases, and the relative importance of

environmental to host factors varies as a continuous spectrum for different diseases. Environmental factors seem to play a small role in the development of genetic diseases compared with infectious diseases or accidents. However, exposure to environmental factors may trigger the clinical manifestation of genetic diseases such as phenylketonuria and glucose-6-phosphate dehydrogenase deficiency. Environmental influences on human health are exerted through exposures to physical, chemical, and biological risk factors, and through related changes in human behavioural responses to those factors. The World Health Organization has released a country-by-country analysis of the impact of environmental factors on health (Pruss-Ustun and Corvalan 2006). These data show huge inequalities but also demonstrate that in every country, people's health could be improved by reducing environmental risks including pollution, hazards in the work environment, ultraviolet radiation, noise, agricultural risks, climate, and ecosystem change. It is estimated that 13 million deaths worldwide could be prevented every year by making environments healthier. Reducing environmental risks could save as many as 4 million lives a year in children alone, mostly in developing countries. In some countries, more than one-third of the disease burden could be prevented through environmental improvements. In 23 countries worldwide, more than 10 per cent of deaths were due to two environmental risk factors: unsafe water, including poor sanitation and hygiene; and indoor air pollution due to solid fuel used for cooking. Around the world, children under 5 years were the main victims and made up 74 per cent of deaths due to diarrhoea and lower respiratory infections. Proper environmental management is the key to prevent the quarter of all illnesses which are directly caused by environmental factors.

Human beings live in environments with many causes of diseases as shown in Table 7.1.1. Environmental causes for human diseases include physical, chemical, and biological agents. The physical component includes non-ionizing and ionizing radiation, noise, vibration, pressure, humidity, temperature, earthquake, landslides, typhoons and hurricanes, snow-storms, and sand-storms. Ionizing radiation includes alpha and beta particles, gamma rays and X-rays. Ionizing radiation may induce spontaneous abortion, congenital malformation, cancers, and haematopoietic disorders through its effects on DNA damage and chromosomal aberrations. Non-ionizing radiation includes ultraviolet rays, visible light, infrared rays, microwaves, and electromagnetic fields. Ultraviolet rays may induce skin cancer and cataract; while electromagnetic fields may induce some cancers. The chemical component includes heavy metals, organic solvents, agricultural chemicals, polycyclic hydrocarbons, and chlorinated organic compounds. Their health effects may be classified as acute toxicogenicity, subacute toxicogenicity, chronic toxicogenicity, carcinogenicity, mutagenicity, and teratogenicity. Some chemicals may persist in the environment and result in bioaccumulation. The biological component includes viruses, bacteria, fungi, parasites, allergens, arthropods, as well as plant and animal toxins. A number of infectious diseases of various organ systems are caused by biological agents. In addition to the acute and subacute symptoms and signs, these infectious agents may also induce chronic diseases such as cancers of the nasopharynx, stomach, liver, bladder, cervix, uteri, and lymphoid and soft tissue, pulmonary diseases, cardiovascular diseases, as well as neurological disorders.

Host components in response to environmental components are also important in the determination of a number of human diseases

Table 7.1.1 Environmental components of causes for human diseases

Component	Category
Physical	Ionizing radiation (α -particles, β -particles, γ -rays, X-rays)
	Non-ionizing radiation (ultraviolet rays, visible light, infrared rays, microwaves, electromagnetic fields)
	Noise
	Vibration
	Pressure
	Humidity and temperature
	Earthquakes and landslides
	Typhoons and hurricanes
	Snow-storms and sand-storms
Chemical	Heavy metals
	Organic solvents
	Agricultural chemicals
	Polycyclic hydrocarbons
	Chlorinated organic compounds
Biological	Viruses
	Bacteria
	Fungi
	Parasites
	Allergens
	Arthropods
	Animal and plant toxins

as shown in Table 7.1.2. Social components of human diseases include built environments, occupational settings, agricultural methods and irrigation schemes, transportation systems, water supply systems, sewage and waste disposal, schooling systems, healthcare systems, social welfare and criminal prevention systems, anthropogenic climate changes, and ecosystem degradation. Behavioural components include substance use, dietary intake, personal hygiene including hand-washing, occupational safety, safe sex, sports and exercise, personal communication and networking, and response to stressful life events. All these host components play very important roles in the development of environmental health hazards. For example, using cleaner fuel such as gas or electricity, using better cooking devices, improving ventilation, or keeping children away from smoke could have a major impact on respiratory infections and diseases among women and children. As estimated by the World Health Organization, reducing levels of air pollution (measured by PM10) as set out in the Air Quality Guidelines would save an estimated 865,000 lives per year. The household interventions could dramatically reduce the death rate. Interventions at the community or national level would involve promoting household water treatment and safe storage, and introducing energy policies, which favour development and health.

Several causal models have been proposed to describe the host–environment interaction in human diseases as shown in Table 7.1.3. The traditional epidemiological triangle emphasizes the equal importance of host, agent, and environment, which are located in three angles of the epidemiological model. Host factors may include the biological characteristics, sociodemographic characteristics and behavioural characteristics listed in Table 7.1.3. The agent

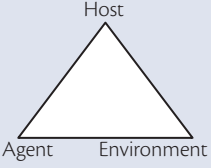

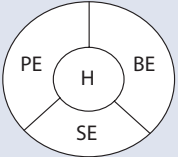

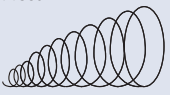

Table 7.1.2 Host components of causes for human diseases

Component	Category
Behavioural	Substance abuse (alcohol, tobacco, betel, drugs)
	Dietary intake (malnutrition, over-nutrition)
	Personal hygiene
	Occupational protection practice
	Stressful life events
	Sports and exercise
	Personal communication and networking
Social	Housing and home safety
	Water supply system
	Sewage and waste disposal
	Transportation system
	Agricultural and irrigational methods
	Working environment
	Industrial hygiene and safety
	Anthropogenic pollution and climate changes
	Ecosystem degradation
	Schooling system
	Healthcare system
	Social welfare and criminal prevention

factor includes the physical, chemical, biological, and social characteristics of causal agent of disease. Environmental factors include living and working environments such as family, school, workplace, and recreation place. The epidemiological triangle model is widely used to develop various strategies to prevent the occurrence of diseases. Host factors may be strengthened through the improvement in nutritional status, optimal rest and exercise, personal hygiene, active and passive immunization, immunomodulation, chemoprevention, and so forth. Agent factors may be controlled through disinfection and sterilization, antibiotic use, prevention of drug resistance, and antiviral therapy. Environmental factors may be improved through clean housing and workplaces, safe water and food supply, hygienic sewage and waste disposal, and others.

The epidemiological triangle model emphasizes the unique causal agent of a specific disease. This model is most appropriate for infectious diseases because the infectious agent is the necessary (unique) cause of a given infectious disease, even though the infectious agent may not be sufficient to cause the given disease. For many infectious agents, not all infected individuals will develop the disease. The one-to-one causal relation between agent (cause) and disease (outcome) may not be observed under this circumstance. The triangle model is not appropriate for most chronic non-communicable diseases. Most chronic diseases have multiple causes. A single agent is neither necessary nor sufficient to cause the disease. The ecological wheel model shown in Table 7.1.3 was proposed to describe the host–environment interaction for human diseases. The wheel model includes an axle (host factors) surrounded by a tyre (environmental factors). No unique single agent is specified for a disease in this model. Environmental factors are further classified into those from the physicochemical environment including energy and chemical substances, living and working infrastructure, and public facilities; biological environmental factors including infectious agents,

Table 7.1.3 Causal models describing host–environment interaction in human diseases

Model	Illustration	Components	Characteristics

Evolutionary spiral		Chronology/stage Health effects/lesions Host Environments	Initiation→ Promotion→ Progression Molecules→ Cells→ Tissues→ Organs → Systemic illness Genes Behaviours Physicochemical environment Biological environment Social environment

animal reservoirs, vectors, and infectious carriers; and social environmental factors including culture, customs, and social networks. Genetic factors are located in the core of the host with the rest of the host factors including lifestyle, personality, dietary intake, and immunity. This causal model emphasizes the importance of ecological balance in the maintenance of the health status of a host. The relative importance of host and various environment factors varies by diseases. For example, genetic factors are most important for the highly inheritable diseases; the biological environment for various infectious diseases; and the social environment for accidents. This wheel model also describes the interactions among host and various environment components.

The ecological wheel does not take the time dimension of disease development into consideration. The development of both acute and chronic diseases follows a specific temporal sequence. This usually starts from contact of causal agent with target cells, through the structural and functional changes as well as proliferation of causal agent and transformed cells, the development of lesions in

affected tissues or organs, the onset of clinical symptoms and signs, to the development of systemic illness. There are various agents and environment factors involved at different stages of the pathological progression. For example, the multistage process of carcinogenesis may be classified into initiation, promotion, progression, invasion, and metastasis. An evolutionary spiral model has been proposed to describe host–environment interactions over the entire natural history of disease as shown in Table 7.1.3 (Chen 1999). At the initial stage, both cause and molecular or cellular change are simple and small, and causal relationship tends to be one-to-one. With disease progression, however, both causes and affected lesions become more and more complicated and involve complex host–environment interactions at different stages.

The evolutionary spiral model is most appropriate for the description of multistage pathogenesis of a disease with a multifactorial aetiology. As shown in Fig. 7.1.1, the development of hepatocellular carcinoma is a multistage process with the involvement of multiple risk factors. A healthy individual may be infected by

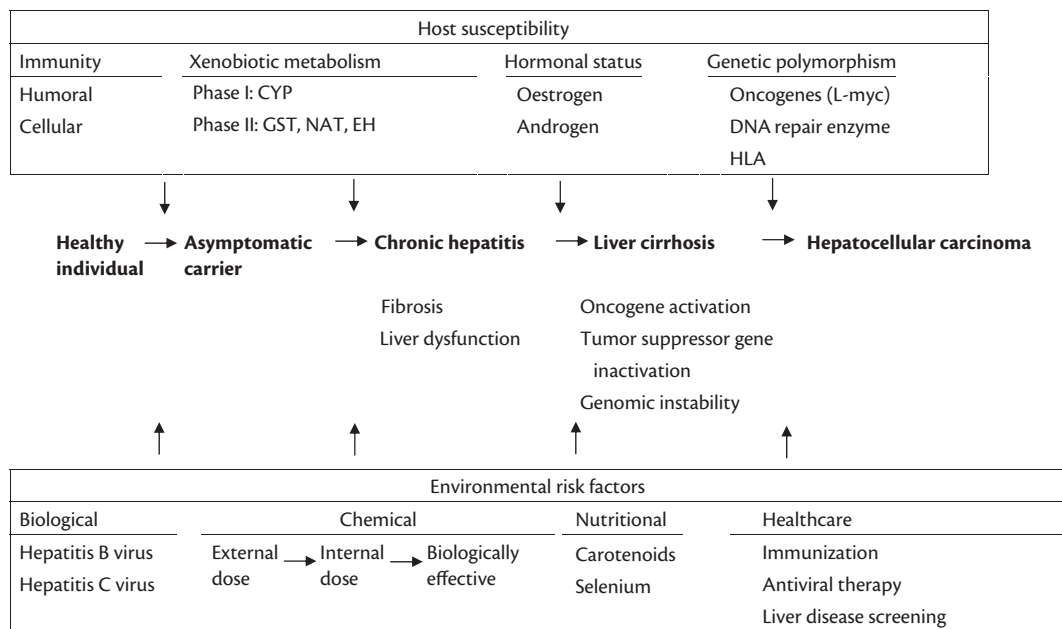

Fig. 7.1.1 Multistage hepatocarcinogenesis with a multifactorial aetiology.

infectious agents such as hepatitis B virus (HBV) and hepatitis C virus and become an asymptomatic carrier. With the long-term progression of the viral hepatitis, the carrier may start to develop chronic hepatitis, liver fibrosis, cirrhosis, and even hepatocellular carcinoma. During the disease development period, there are host and environmental factors that may influence the disease progression at various stages. Chemical carcinogens including aflatoxins, benzo(a)pyrene, and 4-aminobiphenyl as well as micronutrients such as carotenoids and selenium are involved in hepatocarcinogenesis. Host factors including humoral and cellular immunity, xenobiotic metabolism, hormones, and susceptibility genes can modify the progression of chronic hepatitis B. Healthcare factors including immunization, antiviral therapy and abdominal ultrasonographic screening may be used to stop or slow the pathogenic process. This example illustrates how physicochemical, biological, and social environments are important in the entire hepatocarcinogenesis process.

Ecological studies: identification of environmental health hazards at aggregate level

Geographical clustering of endemic diseases in a small area is the most important characteristic of environmental health hazards. An extremely high prevalence of an endemic disease in a confined area always leads to the search for unique environmental risk factors. Ecological studies are often used to compare the morbidity or mortality of environmental disease between endemic and non-endemic areas. In ecological studies, aggregate attributes such as the morbidity of residents in exposed and unexposed areas, rather than individual attributes such as the health status of exposed and unexposed subjects, are analysed and compared. Ecological studies tend to compare health indices in areas with and without the environmental exposure, or to examine quantitatively the correlation between health indices and environmental

exposure in many areas. Some environmental characteristics or co-morbidity rates may be used as surrogate indicators of the causal agents to elucidate the relation between the disease risk and the causal agent. The interpretation of ecological studies may be limited by the potential existence of ecological fallacy, when the agent–disease correlation observed at the aggregate level may not consistently be found at the individual level. However, ecological studies are frequently used to explore environmental component of causes for human diseases.

As an illustrative example, blackfoot disease is an endemic peripheral vascular disorder confined to a limited area on the southwest coast of Taiwan. Clinically the disease starts with numbness or coldness of one or more extremities and intermittent claudication, which progresses to black discoloration, ulcer and gangrene. In end stages of the disease, spontaneous amputation of the distal parts of the affected extremities is common. The disease was hyperendemic in four neighbouring townships in southwestern Taiwan. As the water from shallow wells (6–8 metres in depth) in this area had high salinity, residents in some villages had started to use water from artesian wells (100–200 metres deep) since 1920s. The use of artesian well water was found to be associated with the occurrence of the blackfoot disease, and water samples from artesian wells of the endemic area were found to have high arsenic concentrations which ranged from 0.35 to 1.14 mg/L. Based on the analysis of mortality data, residents in the endemic area of blackfoot disease had significantly elevated mortality from cancers of the bladder, kidney, skin, lung, and liver as shown in Table 7.1.4. Compared with the general population in Taiwan, the standardized mortality ratios for cancer of the bladder, kidney, skin, and lung were threefold greater among residents in the endemic area (Chen et al. 1985).

As the four townships in this endemic area had different prevalence of blackfoot disease, cancer mortality was further compared among townships. It was found that the higher the blackfoot disease prevalence of a township, the greater the age-standardized

Table 7.1.4 Age-standardized mortality ratios¹ of skin and internal cancers in villages of arseniasis-endemic area in southwestern Taiwan by blackfoot disease prevalence and drinking water source

Cancer	Gender	Blackfoot disease endemic area	Township by blackfoot disease endemicity ²					Village by blackfoot disease endemicity ³			Village by types of wells as major drinking water source ⁴

	Female	2.3	1.8	2.3	2.5	2.4							

¹ Mortality rates of general population in Taiwan were used as the standard rates to calculate standardized mortality ratio (Taiwan = 1.0).

² Four townships including Peimen, Husechia, Putai and Ichu with blackfoot disease prevalence of 5.67, 3.87, 2.02 and 0.64 per 1,000, respectively. Age-standardized mortality ratios were calculated for males and females, respectively.

³ A total of 84 villages were classified into three groups by blackfoot disease prevalence: 0, 0.1–5.0 and >5.0 per 1000, respectively. Age–gender-standardized mortality ratios were calculated.

⁴ A total of 84 villages were classified into three groups by type of wells used as major drinking water source: artesian wells only, both artesian and shallow wells, and shallow wells only. Age–gender-standardized mortality ratios were calculated.

Reproduced with permission from Chen CJ et al., Malignant neoplasms among residents of a blackfoot disease-endemic area in Taiwan: High-arsenic artesian well water and cancers, *Cancer Research*, Volume 45, pp. 5895–5899, Copyright © 1985 American Association for Cancer Research.

mortality ratios for cancers of the skin, bladder, lung, and liver. As 84 villages in these four townships also had different prevalence of blackfoot disease and used different types of well water, more refined analyses of cancer mortality at village level were carried out. A significant dose–response relationship between the prevalence of blackfoot disease and the age–sex-standardized mortality ratios for cancers of the skin, bladder, kidney, lung and liver was observed at the village level as shown in Table 7.1.4. Furthermore, biological gradients of cancer mortality were also found by the type of wells used as drinking water source with the highest cancer mortality in villages where only artesian wells were used and the lowest in villages which used only shallow wells. As both blackfoot disease and artesian well use were significantly associated with the arsenic in drinking water, they were used as the surrogate environmental variable for arsenic exposure. It was thus implied that arsenic in drinking water might increase the risk of both skin and internal cancers. However, the best way to assess the cancer risk associated with arsenic in drinking water is to obtain the arsenic levels in drinking water from wells.

The arsenic levels in water of shallow and artesian wells in 42 villages of the blackfoot disease endemic area were available for further analysis of the association between arsenic in drinking water and cancer mortality. As shown in Table 7.1.5, there was a significant dose–response relation between arsenic in drinking water and age-adjusted mortality for cancers of the bladder, kidney, lung, skin, liver, and prostate at the village level (Chen et al. 1988a). A significant dose–response relationship was also observed between arsenic in drinking water and age-adjusted mortality for cardiovascular diseases and peripheral vascular diseases at the village level (Wu et al. 1989). In another ecological correlation study on age-adjusted

cancer mortality of 314 precincts and townships in Taiwan (Chen and Wang 1990), the arsenic level in water of 83,656 wells was tested to derive the average arsenic level in well water in each precinct or township. Both cancer deaths and mid-year population in all study precincts and townships were obtained from the national death certification and household registration system. Based on the weighted multiple regression analysis, there were significant correlations between the average arsenic level in well water and the age-adjusted mortality rates of cancers of the liver, nasal cavity, lung, skin, bladder, kidney, and prostate at the precinct/township level, after adjustment for indices of industrialization and urbanization. In these ecological correlation studies, both disease risk and environmental exposure were measured at a group (village or precinct/township) level. The findings have to be further validated by studies at the individual level, in which potential ecological fallacy and confounding effects of extraneous factors such as cigarette smoking habit are limited.

Ecological studies have also been used to explore possible associations between infectious agents and cancer. Chronic hepatitis B is a worldwide public health challenge. Despite the availability of an effective vaccine, an estimated 350–400 million people are chronically infected with the HBV. Chronic hepatitis B is particularly prevalent in the Asia-Pacific and sub-Saharan Africa regions, where infection is predominantly acquired either during the perinatal period or in the early childhood years. The countries with high incidence of liver cancer are also clustered in the Asia-Pacific and sub-Saharan Africa regions. The significant ecological correlation between the mortality from liver cancer and the prevalence of chronic hepatitis B was also observed among townships in Taiwan. These ecological study findings suggest the importance of chronic

Table 7.1.5 Age-standardized mortality (per 100,000) from skin and internal cancers in villages of arseniasis-endemic area in southwestern Taiwan by arsenic level in well water

hepatitis B in the development of liver cancer, specifically hepatocellular carcinoma. The seroprevalence of antibodies against *Helicobacter pylori* was found to be associated with the mortality from gastric cancer in Taiwan, suggesting *Helicobacter pylori* infection may be a causal agent of gastric cancer. However, the ecological correlation observed at the aggregate level needs further validation by studies at the individual level.

Cross-sectional surveys and longitudinal studies: assessment of environmental health hazards at individual level

Several different study designs have been used to assess the environmental health hazards at the individual level as shown in Table 7.1.6. Based on the time of the collection of disease risk (outcome) and environmental exposure (cause) data, they may be classified into cross-sectional and longitudinal studies. Cross-sectional studies collect the data on disease and exposure at the same time. The most common type of cross-sectional studies is the environmental health survey, in which participants are enrolled from exposed and unexposed areas to collect the

information on health status, exposure to environmental factors, and potential confounding factors. Morbidity estimates from cross-sectional surveys represent disease prevalence rather than incidence. As the disease and exposure data are collected simultaneously, the causal temporality of disease and exposure needs further evaluation. If the environmental exposure is quite consistent over a long period of time before the onset of the disease, the causal temporality may be considered correct. Longitudinal studies may be further classified into case-control and cohort studies according to the enrolment of study participants. Conventional case-control studies recruit incident cases and matched controls from healthcare institutions or the community, and collect the history of exposure to environmental factors through questionnaire interviews. While the causal temporality is accounted for, the information on environmental exposure history may be subject to recall and other biases. If there were detailed records of long-term exposure history, the bias may be reduced significantly. Conventional cohort studies recruit exposed and unexposed healthy participants from community or workplace, and follow the cohort until an adequate proportion of participants develop the disease under study. While there is no recall bias of the exposure information, it may be limited by participants being lost to follow-up. If data from disease registration systems or health insurance databases were available, the loss to follow-up may be solved through computerized data linkage.

Returning to blackfoot disease as an illustrative example, in a community-based cross-sectional survey of 40,421 residents in 37 villages in the endemic area in southwestern Taiwan, the relationship between status of skin cancer and blackfoot disease in participants, and arsenic in well water was examined (Tseng 1977). As shown in Fig. 7.1.2 there was a significant dose-response relationship between skin cancer and blackfoot disease, and arsenic concentrations in the drinking water for most age and sex groups. There was a significant coexistence of both skin cancer and blackfoot disease. In a community-based case-control study, a total of 353 pairs of blackfoot disease cases and matched controls were interviewed (Chi and Blackwell 1968). The length of residing in the endemic villages was significantly associated with the risk of developing blackfoot disease in a dose-response relation. While all 353 (100 per cent) blackfoot disease cases had ever used artesian well water as the principal source of drinking water during the 15 years before onset, only 233 (66 per cent) matched controls had consumed artesian well water ($p < 0.001$). Blackfoot disease cases had lower educational level and socioeconomic status than matched controls. In another case-control study on 241 blackfoot disease patients and 759 matched healthy controls, questionnaire

Table 7.1.6 Major study designs of investigation on environmental health hazards at individual level

Temporality between disease and exposure	Collection of disease and exposure data	Study subjects selection	Limitations	Association estimates
Cross-sectional	Simultaneous	Random sample of population	Temporal correctness	Odds ratio
Longitudinal	Retrospective (retrieval of previous exposure)	Affected cases and unaffected controls	Recall bias	Odds ratio
Longitudinal	Prospective (follow-up of future disease)	Exposed and unexposed cohorts	Loss of follow-up	Hazard ratio

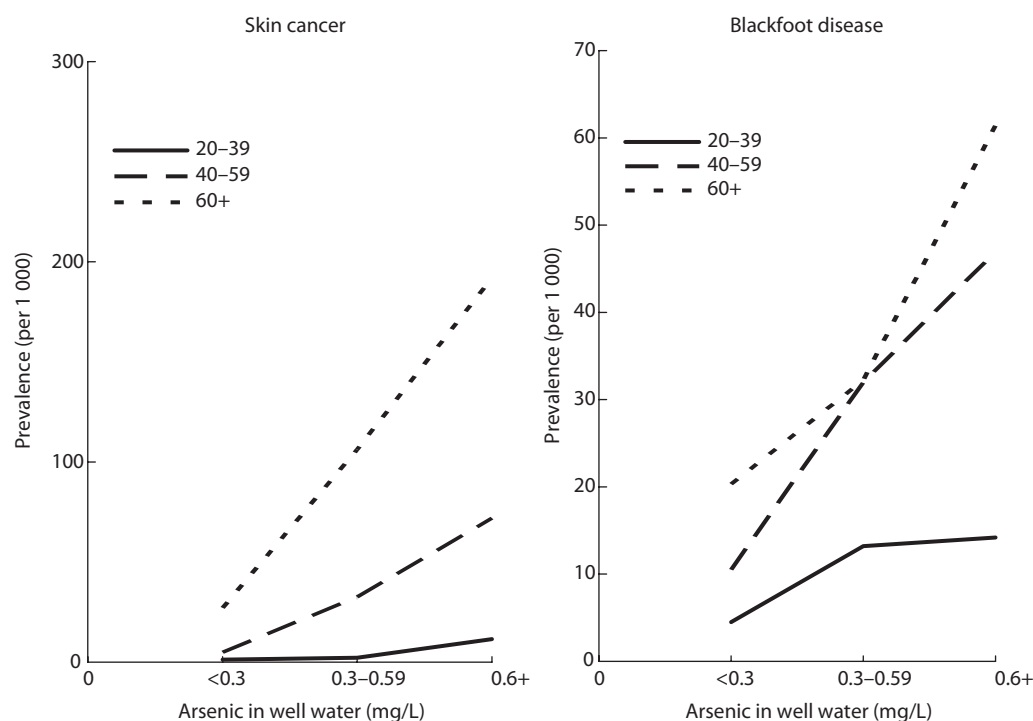

Fig. 7.1.2 Dose-response relationship between arsenic in well water and prevalence of skin cancer and blackfoot disease.

interviews were carried out to obtain information on the history of consuming artesian well water, diet, alcohol intake and cigarette smoking, as well as the presence of arsenic-induced skin keratosis and cancer, and blackfoot disease in first-degree relatives (Chen et al. 1988b). There was a significant dose-response relationship between the risk of developing blackfoot disease and the duration of consumption of artesian well water. In addition, arsenic-induced skin lesions, family history of blackfoot disease, and undernourishment were also associated with the development of blackfoot disease independent of the duration of consuming artesian well water.

In a cohort study of cause-specific mortality of 789 blackfoot disease patients followed for 15 years (Chen et al. 1988b), age-sex-standardized mortality ratios were derived for blackfoot disease patients using the mortality rates of the general population in Taiwan and the blackfoot disease endemic area as the standard rates, respectively. As shown in Table 7.1.7, patients of blackfoot disease had significantly increased mortality from cardiovascular disease and cancers of the bladder, skin, lung, and liver compared to two reference populations. In another case-control study on cancers of bladder, lung, and liver in the endemic area of blackfoot disease (Chen et al. 1986), the duration of consuming artesian well water was significantly associated with three cancers in a dose-response relationship after adjustment for age and sex.

A community-based health survey study was carried out in three blackfoot disease-hyperendemic villages to examine the associations between arsenic in drinking water and various chronic diseases. A total of 1571 residents aged over 30 years were interviewed by public health nurses, and 1071 of them had health examinations. Residents in these villages started using artesian wells as the

All rights reserved. DOI: 10.1161/01.ATV.8.5.452.

principal drinking source in early 1910s, and shifted to the public water supply system using surface water from a distant reservoir in early 1970s. The arsenic level in water of artesian wells of the blackfoot disease-hyperendemic villages was surveyed in the early 1960s. As residents in a given village shared a few wells together, the median arsenic level of the water from the shared wells was used as the level of arsenic in drinking water for residents of the village. As a participant might migrate from one village to another, a detailed life history of residence and consumption of artesian well water was obtained through a structured questionnaire interview. The cumulative arsenic exposure was derived by the formula $\Sigma(C_i \times D_i)$; where C_i was the median arsenic level in water of shared wells of a village in which the participant lived, and D_i was the duration of drinking artesian well water in the village during the consecutive period i . The average arsenic exposure level in drinking water of a participant was derived by $\Sigma(C_i \times D_i)/\Sigma(D_i)$. Residents in hyperendemic villages of blackfoot disease had a significantly higher age-specific prevalence of diabetes mellitus (Lai et al. 1994) and hypertension (Chen et al. 1995) than residents in non-endemic areas. Furthermore, there was a significant dose-response relationship between the cumulative arsenic exposure and prevalence of diabetes mellitus (Lai et al. 1994), hypertension (Chen et al. 1995), peripheral vascular disease based on Doppler ultrasonography

(Tseng et al. 1996), carotid atherosclerosis based on duplex ultrasonography (Wang et al. 2002), electrocardiogram-based ischaemic heart disease (Tseng et al. 2003), cataract (See et al. 2007), and pterygium (Lin et al. 2008) as shown in Table 7.1.8. Follow-up studies also found a significant biological gradient of incidence of skin cancer (Hsueh et al. 1997) and lethal ischaemic heart disease (Chen et al. 1996a) with increasing cumulative arsenic exposure as also shown in Table 7.1.8.

Table 7.1.8 also shows summary data from another survey of well-water arsenic and health status in northeastern Taiwan that involved a total of 8102 residents in four townships. Residents in these townships had their own tube wells in their backyards. The arsenic levels in well water of these households were tested in early 1990s. The public water supply system using surface water was introduced in this area in early 1990s, and its coverage was as high as 95 per cent in the year 2000. Cerebrovascular disease, especially cerebral infarction, was identified from home-visit personal interviews and ascertained through the review of hospital medical records (Chiou et al. 1997). These revealed a dose-related increase in the risk of cerebral infarction with higher cumulative arsenic exposure.

In several cohort studies of participants enrolled from the endemic areas of arseniasis in southwestern and northeastern

Reproduced from *Journal of Asian Earth Sciences*, Volume 77, Yang TY et al., Lifetime risk of urothelial carcinoma and lung cancer in the arseniasis-endemic area of northeastern Taiwan, pp. 332–337, Copyright © 2013, with permission from Elsevier, <http://www.sciencedirect.com/science/journal/13679120>.

Taiwan, the occurrence of cancers was identified and ascertained through computerized data linkage with national cancer registry and death certification profiles. A dose–response relation was observed between long-term arsenic exposure from drinking well water and incidence of urothelial carcinoma (Chiou et al. 2001) and lung cancer (Chen et al. 2004). Based on follow-up data from northeastern Taiwan, the cumulative lifetime risk of lung cancer and urothelial carcinoma was found to increase with the arsenic concentration in well water (Fig. 7.1.3) (Yang et al. 2013). It is important to be aware of the possibility of temporal variations in concentration of the causal agent in various environmental media, individual variations in frequency and quantity of contact with the contaminated environmental media, and variations in detection limit of various exposure assessment methods. It is essential to ensure accuracy in the assessment of exposure to environmental factors in all cross-sectional surveys, case–control studies, and cohort studies in order to identify and characterize the environmental health hazards efficiently and effectively.

Several case–control studies have assessed the association between risk of hepatocellular carcinoma, chronic hepatitis B infection, and seropositivity of hepatitis B surface antigen (HBsAg) (Chen et al. 1997; You et al. 2004). A statistically significant association between hepatocellular carcinoma and HBsAg serostatus was found in all cross-sectional case–control studies. It should be noted that the HBsAg serostatus determined at the time of the diagnosis of hepatocellular carcinoma, might not reflect the serostatus long before the onset of the cancer. However, since most HBsAg-seropositive participants become chronic carriers in early childhood, this would support a longer-standing temporal association between HBsAg seropositivity and hepatocellular carcinoma in such cases. Another case–control study further evaluated the importance of hepatitis B e antigen (HBeAg) in the development of hepatocellular carcinoma (Chen et al. 1991). The relative risk of hepatocellular carcinoma was 58-fold higher for those who were seropositive for both HBsAg and HBeAg, 17-fold higher for seropositives for HBsAg only, as compared with those who were seronegative on both markers as reference. As both HBsAg and HBeAg disappear gradually with increasing age, their seroprevalence estimated at the onset of hepatocellular carcinoma is much lower than those in childhood or young adulthood. An insurance-based cohort study of 3,454 chronic HBsAg carriers

and 19,253 non-carriers in northern Taiwan had confirmed the high risk of hepatocellular carcinoma for chronic HBsAg carriers compared with the non-carriers, with a relative risk greater than 100-fold (Beasley et al. 1981). Another community-based cohort study on 2361 carriers and 9532 non-carriers of HBsAg in seven townships in Taiwan showed the importance of HBeAg serostatus in the development of hepatocellular carcinoma in addition to HBsAg serostatus (Yang et al. 2002). These observational studies suggest the most effective and efficient ways to reduce the risk of hepatocellular carcinoma in Taiwan are vaccination to prevent hepatitis B infection and appropriate antiviral treatment of patients with chronic hepatitis B infection.

Intervention trials: validation of environmental health hazards through preventive intervention

It is unethical to carry out experimental studies on human beings to validate the suspected effects of environmental health hazards identified from observational studies discussed earlier. However, intervention trials may be used to evaluate possible effects of environmental agents on disease risk by removing the agents from the environment. Intervention trials may be classified as individual or cluster trials depending on whether individual subjects or clusters such as households, schools, or communities are allocated to the intervention. Intervention trials may also be classified as controlled and uncontrolled trials depending on the inclusion of a comparable control group or not. In controlled trials, the effect of intervention on environmental health hazards is evaluated by the comparison of disease occurrence between experimental and control groups. In uncontrolled trials, the effect of intervention is assessed by the comparison of disease occurrence of the experimental group before and after the intervention.

The implementation of a public water supply system, which used uncontaminated surface water from distant reservoirs, in the blackfoot disease-endemic area of southwestern Taiwan was started in the early 1960s and completed in the 1970s. The arsenic-induced health hazards identified from observational studies could thus be validated through the comparison of the secular changes in morbidity and mortality of arsenic-induced diseases in the endemic and non-endemic areas. In a series of

studies, cause-specific standardized mortality ratios of residents in the blackfoot disease endemic from 1971 to 2003 were calculated using the general population in Taiwan as the standard population. Cumulative sum techniques were used to detect the occurrence of changes in the standardized mortality ratios. A significant decline in mortality from ischaemic heart disease (Chang et al. 2004), renal disease (Chiu and Yang 2005), peripheral vascular disease (Yang 2006), and cancers of the lung (Chiu et al. 2004b), kidney (Yang et al. 2004), and bladder (Yang et al. 2005) was observed for both males and females in the southwestern endemic area of blackfoot disease. A significant decline in mortality from liver cancer (Chiu et al. 2004a) and diabetes mellitus (Chiu et al. 2006) was observed for females but not males. Based on the reversibility criterion, it was concluded that associations between arsenic exposure and various health effects was very likely to be causal. Although the findings are quite consistent with observational studies mentioned earlier, there are several issues which need further clarification: (1) classification of underlying causes of death may vary by area and time. It is necessary to examine whether the variations in the classification of underlying causes in death certificates are comparable in different areas over the study period. (2) Competing causes of death may be quite different between the endemic area and Taiwan as a whole. Arsenic has a pleiotropic health effect that induces various cancers, circulatory diseases, diabetes mellitus, hypertension, renal disease, and so forth. A person may die with several arsenic-induced diseases. It is thus difficult to select an underlying cause of death for an arsenic-exposed person. (3) Mortality associated with a disease is a function of the incidence and fatality of the disease. High mortality may imply an increased incidence and/or an elevated fatality rate. It is better to analyse incidence rather than mortality to clarify the causal association between agent and disease. (4) Risk factors other than arsenic may be important confounding factors, such as habits of cigarette smoking and alcohol drinking, chronic infection with hepatitis viruses, and obesity. They are not taken into consideration in the mortality analysis. It is thus more convincing to compare the secular changes in the incidence of arsenic-induced diseases after the implementation of public water supply system. Furthermore, age-cohort-period analysis may also help the identification of susceptible ages at exposure to arsenic and the assessment of reversibility effect of intervention.

A nationwide vaccination programme aimed at eradicating HBV infection was launched on 1 July 1984 in Taiwan (Chien et al. 2006). It was the first universal hepatitis B vaccination programme for newborns in the world. During the first 2 years (July 1984 to June 1986) of the programme, only newborns born to high-risk (HBsAg-positive) mothers were vaccinated. Since July 1986, however, all newborns were vaccinated. The programme was further extended to the preschool children who had not received vaccination as neonates since 1987. There has been a dramatic decrease in the HBsAg carrier rate and HBV infection rate among children and adolescents born after 1984 demonstrating the programme not only successfully prevented the perinatal transmission of HBV but also reduced the risk of horizontal transmission of HBV among children (Hsu et al. 1999). Recent studies in Taiwan also demonstrated a significant decline in the mortality from fulminant hepatitis in infants (Kao et al. 2001) and

the incidence of hepatocellular carcinoma (Chang et al. 1997) in children since the nationwide hepatitis B vaccination programme was launched. Even more striking has been the effectiveness of the national hepatitis B vaccination programme in reducing long-term risk of infant fulminant hepatitis, chronic liver disease, and hepatocellular carcinoma, as shown by the data from a recent report, which are summarized in Table 7.1.9 (Chiang et al. 2013). These important findings demonstrated that hepatitis B vaccination not only protected children from becoming chronic HBV carriers but also protected them from developing fulminant hepatitis, chronic liver diseases, and hepatocellular carcinoma. These are among the first studies to demonstrate the prevention of human cancer through vaccination. Through the strong evidence of a striking decline in childhood incidence of hepatocellular carcinoma after the introduction of the national vaccination programme, the causal relation of chronic hepatitis B infection with hepatocellular carcinoma is well confirmed. However, the elucidation of the failure of hepatitis B vaccination to eliminate all childhood hepatocellular carcinoma requires further study at the individual rather than national level.

Before the Second World War, endemic goitre was highly prevalent in mountainous areas in Taiwan. A national survey showed a prevalence as high as 70 per cent in some aboriginal townships in mountainous areas. The prevalence of goitre in pigs was found to be significantly higher in the goitre-endemic area than non-endemic area. It was debated whether dietary deficiency in iodine or goitrogenic foodstuff intake was the major cause of the endemic goitre. The use of iodine tablets to supplement dietary iodine intake was found to be effective in lowering the prevalence of endemic goitre in school children, but it was considered costly and inconvenient. In order to identify an effective and efficient prevention strategy at the community level, a controlled community intervention trial on iodized salt was carried out in two townships in northern Taiwan (Chen et al. 1976). All the dietary salt used in experimental and control townships was strictly provided by the research team. Before the implementation of the community trial, the endemic goitre prevalence among schoolchildren was similarly high. One year after the trial, the prevalence of endemic goitre in the experimental township was significantly lower than in the control township. While the study did not rule out the possible effects of the intake of goitrogenic foodstuff, iodine deficiency was confirmed to be the most important risk factor for endemic goitre in Taiwan. A nationwide salt iodization programme supported by UNICEF was implemented, and the goitre prevalence has been drastically reduced since then. As there may be changes in dietary intake of iodine other than iodized salt, it is essential to monitor and adjust the level of iodine in the salt to prevent thyroid toxicity due to excessively high intakes of iodine.

Gene–environment interaction in environmental health hazards: identification and application of molecular and genomic biomarkers

The risk of developing an environmental disease may vary in different persons exposed to the same environment. In other

words, there exists a host variation in the susceptibility to diseases caused by environmental factors. The individual susceptibility may come from genetic or behavioural components. For example, poor nutritional status and arsenic methylation capability may modify the risk associated with arsenic-induced health hazards including cancers and cardiovascular diseases. Multiple risk factors including cigarette smoking, aflatoxin exposure, antioxidant deficiency, and serum androgen levels are all important risk factors to hepatitis B-induced hepatocellular carcinoma. Some environmental co-factors are difficult to detect and quantify unless biomarkers are used. Many studies have been carried out in recent decades on changes in the structures and functions of macromolecules, cells, tissues, and organ systems in response to exposures to environmental risk factors, to ascertain if the preclinical lesions of environmental diseases could be detected at an early stage which would allow more timely intervention. More recently, the dramatic advances in genomic research technologies have enabled more extensive investigations into the polymorphisms and mutations of genes of host and biological agents and the effects of gene–gene and gene–environment interactions.

Various biomarkers of exposure, effect, and susceptibility of human diseases have been identified and applied in studies on environmental health hazards. The biomarkers for the exposure to environmental risk factors include molecular dosimetry of internal dose and biologically effective dose. The biomarkers for the effect include early biological changes, altered structures and functions of target organs, and preclinical lesions. The susceptibility biomarkers include both genetic and acquired susceptibility. As an illustration, since the development of chronic arsenic poisoning is a multistage pathogenesis, a series of biomarkers of arsenic-induced health hazards have been developed and applied as shown in Table 7.1.10 (Chen et al. 2005). There are several biomarkers of short-term internal dose for ingested arsenic including levels of arsenic in blood, urine, hair, and finger or toe nails. Arsenic in urine, hair, and nails are better biomarkers for short-term exposure than arsenic in blood. The cumulative arsenic exposure to arsenic from drinking water was found to be significantly associated with relative proportion of monomethylarsonic acid and dimethylarsinic acid in urine; but not with urinary levels of arsenite, arsenate, and organic arsenic. Skin hyperpigmentation and palmo-plantar hyperkeratosis, characteristic dermatological lesions induced by long-term exposure to arsenic, are excellent clinical biomarkers for long-term exposure to ingested arsenic. The proportion of monomethylarsonic acid in total urinary arsenic level is an important marker for the biologically effective dose of ingested arsenic. The biomarkers of molecular changes induced by ingested arsenic include plasma levels of reactive oxidants and inflammatory molecules such as chemokine C-C motif ligand 2/monocyte chemoattractant protein-1 (CCL2/MCP1). The arsenic-induced cellular changes include sister chromatid exchanges, micronuclei and chromosomal aberrations in peripheral lymphocytes and urothelial cells; as well as chromosomal loss and gain detected by comparative genomic hybridization and loss of heterozygosity in urothelial cells. Biomarkers of subclinical changes include carotid atherosclerosis, QT prolongation, and increased dispersion detected by electrocardiogram, retarded peripheral neural conduction, and retarded neurobehavioral function. The biomarkers

Table 7.1.10 Molecular and genomic biomarkers of exposure, effect, and susceptibility of arsenic-induced health hazards

Category	Group	Biomarkers
Exposure	Internal dose	
	Short term	Arsenic in urine, hair, and nail
	Long term	Relative proportion of monomethylarsonic acid and dimethylarsinic acid in urine Skin hyperpigmentation and hyperkeratosis
	Biologically effective dose	Monomethylarsonic acid in urine
Effect	Molecular changes	Reactive oxidants in blood Inflammatory molecules in blood
	Cellular changes	Sister chromatid exchanges, micronuclei, chromosomal aberrations in target cells Chromosomal loss/gain and loss of heterozygosity in target cells
	Subclinical changes	QT abnormality in electrocardiogram Carotid atherosclerosis Retarded peripheral neural conduction Retarded neurobehavioural function
Susceptibility	Genetic susceptibility	Xenobiotic metabolism enzymes Arsenic methylation enzymes DNA repair enzymes Oxidative stress-related enzymes Serum carotene level
	Acquired susceptibility	

of susceptibility to arsenic-induced health hazards include low serum level of carotenoids and genetic polymorphisms of enzymes involved in xenobiotic metabolism, arsenic methylation, oxidative stress, and DNA repair.

In the multistage hepatocarcinogenesis of chronic hepatitis B, there are many other risk factors that modify the risk of developing hepatocellular carcinoma (Chen and Chen 2002). Biomarkers associated with hepatitis B-induced hepatocellular carcinoma are shown in Table 7.1.11. HBV infection markers include HBsAg, HBeAg, antibodies against hepatitis B core antigen (anti-HBc), antibodies against HBsAg (anti-HBs), antibodies against e antigen (anti-HBe), as well as serum levels of HBV DNA (viral load) and HBsAg. Different HBV infection markers have different associations with the development of hepatocellular carcinoma. In addition to the seropositivity of HBsAg and HBeAg, serum HBV DNA level is associated with an increasing risk of cirrhosis and hepatocellular carcinoma in a dose–response relation (Chen et al. 2006; Iloeje et al. 2006). Different genetic characteristics of HBV are also associated with different risk of liver cirrhosis and hepatocellular carcinoma. The genotype C, basal core promoter A1762T/G1764A mutant, and pre-S mutant of HBV are significantly associated with an increased risk of liver diseases; while the precore stop codon

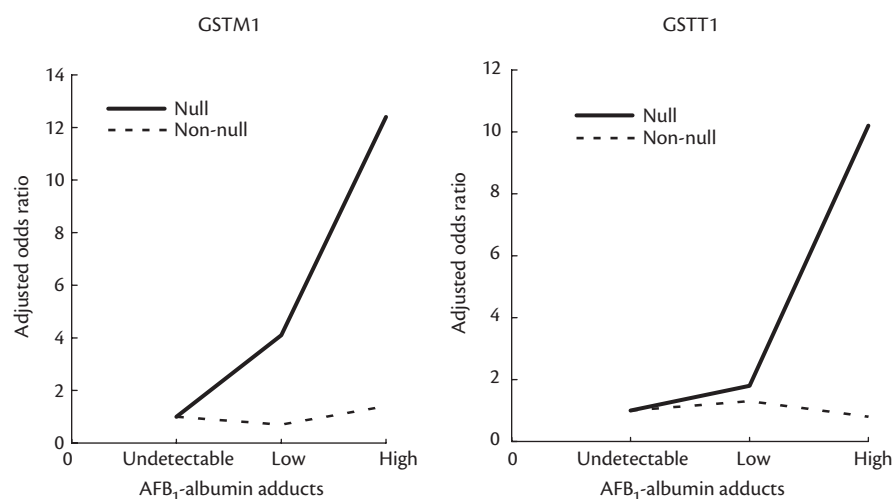

Table 7.1.11 Molecular and genomic biomarkers associated with hepatitis B virus-caused hepatocellular carcinoma

Category	Group	Biomarkers
Exposure	Hepatitis B virus	HBsAg/HBeAg seropositivity Serum HBV DNA level (viral load) Genotype Mutants
	Aflatoxins	Serum HBsAg level Urinary levels of metabolites and guanine adducts
	Tobacco smoke	Serum level of albumin adducts DNA adducts of 4-aminobiphenyl and polyaromatic hydrocarbons HBsAg-seropositivity and normal ALT
Effect	Asymptomatic carriers	Elevated ALT, liver fibrosis
	Chronic hepatitis	Liver fibrosis, cirrhosis, failure
	Cirrhosis	Anti-HBs-seropositivity Serum levels of androgen and oestrogen HLA
Susceptibility	Immunity	Xenobiotic metabolism enzymes
	Hormonal status	DNA repair enzymes
	Genetic polymorphisms	Hormone metabolism enzymes and receptors Serum levels of carotenoids and selenium
	Nutritional intake	

G1896A mutant is associated with a decreased risk. Both quantitative and qualitative characteristics of HBV are important in the development of hepatocellular carcinoma.

Dietary exposure to aflatoxins and habits of cigarette smoking, alcohol drinking, and betel quid chewing have been found to increase the risk of hepatitis B-related hepatocellular carcinoma. Due to the difficulties in measuring dietary exposure to trace amount of aflatoxins and environmental exposures to tobacco smoke, several biomarkers are used for the molecular dosimetry of aflatoxin and tobacco smoke exposures. These include metabolites in urine as biomarkers for internal dose, and macromolecular adducts as biomarkers for biologically effective dose. The hepatic DNA adducts of 4-amino-biphenyls and polyaromatic hydrocarbons are used to measure the biologically effective dose of exposures to tobacco smoke, while DNA and albumin adducts of aflatoxin B₁ were used as biomarkers of biologically effective dose. There is a dose-response relation between exposure to hepatotoxins and risk of hepatocellular carcinoma. There are significant synergistic effects on hepatocellular carcinoma between chronic hepatitis B and environmental hepatotoxins. The hepatocarcinogenesis process progresses from asymptomatic carrier status, chronic hepatitis, cirrhosis, to hepatocellular carcinoma. There are several biomarkers which may be used for the detection of various precancerous lesions.

The effect of environmental hepatotoxins on the hepatitis B-induced hepatocellular carcinoma is modified by genetic polymorphisms of enzymes related to xenobiotic metabolism. Genetic polymorphisms of cytochrome P450 (CYP) enzymes 1A1 and 2E1, glutathione S-transferase (GST) M1 and T1, N-acetyltransferase 2 were found to modify the associations with hepatocellular carcinoma for chemical carcinogen exposure and low micronutrient intake among those with chronic HBV infection. As shown in Fig. 7.1.4 a significant dose-response relation between risk of hepatocellular carcinoma and serum level of aflatoxin B₁ albumin adducts is observed in chronic HBV carriers with null genotype of glutathione S-transferase (GST) M1 or T1, but no dose-response relation is observed for carriers with wild genotypes (Chen et al. 1996b). Elevated serum testosterone level is associated with an increase in the risk of HCC. This association

**Fig. 7.1.4** Modifying effect of genotypes of glutathione S-transferase (GST) M1 and T1 on the dose-response relationship between serum level of aflatoxin B₁(AFB₁)-albumin adducts and risk of hepatocellular carcinoma.

Reproduced from *The American Journal of Human Genetics*, Volume 59, Issue 1, Chen CJ et al., Chronic hepatitis B carriers with null genotypes of glutathione S-transferase M1 and T1 polymorphisms who are exposed to aflatoxins are at increased risk of hepatocellular carcinoma, pp. 128–134, Copyright © 1996 by The American Society of Human Genetics, with permission from Elsevier, <http://www.sciencedirect.com/science/journal/00029297>.

is modified by genetic polymorphisms of androgen receptor (Yu et al. 2000). The highest risk of hepatitis B-related hepatocellular carcinoma was observed among those who have elevated serum level of testosterone and high-risk genotype of androgen receptor. Furthermore, the combination of putative high-risk genotypes of androgen receptor, CYP17, and steroid 5 α -reductase is associated with highly elevated risk of hepatocellular carcinoma suggesting a significant additive effect of gene–gene interaction in the human host (Yu et al. 2001). Low serum levels of micronutrients including carotenoids and selenium are associated with an increased risk of HBV-caused hepatocellular carcinoma. The interactive effects on human health between biological and chemical agents in the environment are complicated and deserve further scrutiny.

Risk calculators of human diseases: combination of multiple biomarkers for prediction of long-term risk of disease

The prediction of disease risk is important for the planning and evaluation of public health programmes aimed at controlling the disease. Risk calculators of many diseases, especially cardiovascular diseases, have been developed and widely applied. As there are many risk predictors for most diseases, it is necessary to integrate several predictors into one measure of absolute risk using a regression model. Uncertainty about clinical interpretation of a single abnormal biomarker may be improved by the development of risk calculators based on the combination of multiple biomarkers. The risk calculator also allows for appropriate recognition of clinically important risk in persons with several but seemingly marginal risk factors that individually may otherwise not raise clinical concerns.

As described earlier, there are several risk predictors of hepatocellular carcinoma in patients affected with chronic hepatitis B. Based on the long-term follow-up findings of a community-based prospective cohort study to elucidate the natural history of chronic hepatitis B (REVEAL-HBV study), several risk calculators for predicting long-term risk of hepatocellular carcinoma have been developed and validated (Yang et al. 2010, 2011). In the most updated risk calculator derived from the REVEAL-HBV Study (Lee et al. 2013), age, sex, family history of hepatocellular carcinoma, serum alanine transaminase (ALT) level, HBeAg serostatus, serum HBV DNA, serum HBsAg level, and HBV genotype are included in the regression model. Integer risk scores are assigned to different categories of various risk predictors as shown in Table 7.1.12. The nomogram showing 5-, 10-, and 15-year cumulative risk of hepatocellular carcinoma by sum of risk score is illustrated in Fig. 7.1.5. For example, a 64-year-old man with a serum ALT level > 45 IU/L, a family history of hepatocellular carcinoma, and a HBeAg-seropositive status with genotype C infection has a sum of risk score of $6 + 2 + 2 + 2 + 7 = 19$. His cumulative risk of developing hepatocellular carcinoma after 5, 10, and 15 years is estimated at around 40 per cent, 80 per cent, and 90 per cent, respectively. This risk calculator was found to have a high sensitivity, specificity, and discriminating capability. The risk calculators for many other diseases may also be developed if there were good large-scale long-term cohort studies on the diseases.

Table 7.1.12 Risk scores assigned to predictors of long-term risk of hepatocellular carcinoma caused by chronic hepatitis B

Baseline hepatocellular carcinoma predictor	Risk score
Age	
30–34	0
35–39	1
40–44	2
45–49	3

Promotion of public health through environmental health intervention

With increasing globalization, environmental pollution or infectious disease outbreaks in one country may result in environmental disasters and health hazards in both adjacent and remote countries. Public health can be promoted through environmental health interventions including the prevention of air, water, and soil pollution with chemicals or biological agents; the reduction in exposures to ultraviolet, ionizing radiation, noise,

and electromagnetic fields; improvement of built environments including housing, land use patterns, and roads; minimization of carbon dioxide emission, global warming, severe climate change, and ecosystem deterioration; optimization of agricultural methods and irrigation schemes; and promotion of occupational safety and security, and so forth. Many environmental health interventions are more cost-effective compared with other kinds of health-sector efforts. These interventions often yield long-term benefits in addition to immediate health improvements. Reduction in the burden of environmental diseases may help the eradication of extreme poverty and hunger, the achievement of universal primary education, the promotion of gender equality and women's empowerment, the reduction in child mortality, the improvement in maternal health, the maintenance of environmental sustainability, and the control of epidemics including AIDS/HIV, malaria, tuberculosis, and other infectious diseases. Global partnerships need to be strengthened to achieve interrelated goals of health, environmental sustainability, and development.

Radiation and public health

Leeka Kheifets, Adele Green,
and Richard Wakeford

Introduction to radiation and public health

The electromagnetic spectrum encompasses frequencies that range from above approximately 10^{20} hertz (Hz) for ionizing radiation at the high end of the spectrum to static fields and power frequencies of 50–60 Hz at the low end. Between the two ends of the spectrum, in order of decreasing frequency, are ultraviolet radiation, visible light, infrared radiation (IR), microwaves, and radio waves (Fig. 7.2.1). This chapter reviews sources and health effects of human exposure to ionizing and non-ionizing radiation and reviews policies for limiting human exposure where appropriate.

The focus of research and our knowledge of the health effects of these forms of energy have been driven, at least partly, by the prevalence of exposure to the general public, although valuable additional information has been derived from occupational studies of high exposure. Our understanding varies: for ionizing radiation, ultraviolet radiation, and extremely low-frequency (ELF) fields numerous state-of-the-art epidemiological and toxicological investigations, encompassing a variety of end points, have been undertaken; a lot of the recent research has been on radiofrequency (RF) fields, but focused on the cell phone use and tumours of the head and neck, with less attention to other sources and outcomes; although numerous studies of static fields have been completed, here too, much of the key research is yet to be done; for IR and intermediate frequencies only scant information is available.

Technological developments involving exposure to electromagnetic fields (EMFs) bring social and economic benefits to large sections of society but the health consequences of these developments can be difficult to predict and manage. As countries increase their capacity to generate and distribute electricity and take advantage of the many new technologies—such as telecommunications—to improve lifestyle and work efficiency, exposures to electric and magnetic fields from 0 to 300 GHz (non-ionizing radiation) have been increasing rapidly. In this chapter, our main emphasis is on exposures common in everyday life rather than occupational exposures. When relevant, we also consider separately exposures from medical applications, as these exposures are commonly higher, but carry a different risk/benefit ratio for the exposed individuals.

Static fields

Sources and environmental levels

For a steady current in a circuit corresponding to zero-frequency (static fields), the charge density at any point of the circuit is

constant, and therefore, the electric fields are constant in time. Since magnetic fields are created by moving electric charges, magnetic fields are also constant for static fields. The unit of measurement for magnetic fields is tesla (T). Another commonly used unit in engineering sciences is gauss (G); one T is equivalent to 10,000 G. Environmental exposure levels are described in microtesla (μT), or 10^{-6} T.

There is a natural static magnetic field that originates from the electric current flowing in the upper layer of the Earth's core, as well as solar activity and atmospheric processes. There are significant local differences in the strength of this field: the vertical component of the field reaches a maximum of about 70 μT at the magnetic poles, and approaches zero at the magnetic equator; conversely the horizontal component is close to zero at the poles and is a maximum of just over 30 μT at the magnetic equator.

In addition to the earth's magnetic field are man-made magnetic fields of significantly higher strength. Major sources of exposure to the general public are transportation and magnetic resonance imaging (MRI). In general, electrified railway systems produce some of the largest static field levels encountered by the general public. Static fields up to several tens of microtesla have been reported inside trams operating on direct current (European Commission 1996). Modern magnetic levitation (maglev) systems use very high fields (around 1 T) directly on the rails; inside the trains fields vary between 50 μT and 10 mT depending on the cabin design. MRI systems have proliferated in recent years and there are currently many thousands worldwide. The static magnetic fields are in the range of 0.2–3 T for systems for routine clinical use. MRI also utilizes much smaller time-varying gradient magnetic fields and radiofrequency radiation. Medical applications with the potential of using fields up to 10 T have been developed and are beginning to be used (Gowland 2005).

Sources of exposure that are either relatively uncommon or small include steel construction materials, high-voltage direct current (DC) transmission lines, headphones and telephone speakers, and steel-belted radial tyres. Use of magnetic plasters, blankets, and mattresses for therapeutic properties have surface magnetic flux densities of about 50 mT but decay quickly within a few millimetres and are not used widely (European Commission 1996). High occupational exposures to static fields are encountered in several industrial processes including aluminium and chlorine production, gas welding, and in accelerator research.

Health effects

The three established biophysical mechanisms are magnetic induction, and magneto-mechanical and electronic interactions.

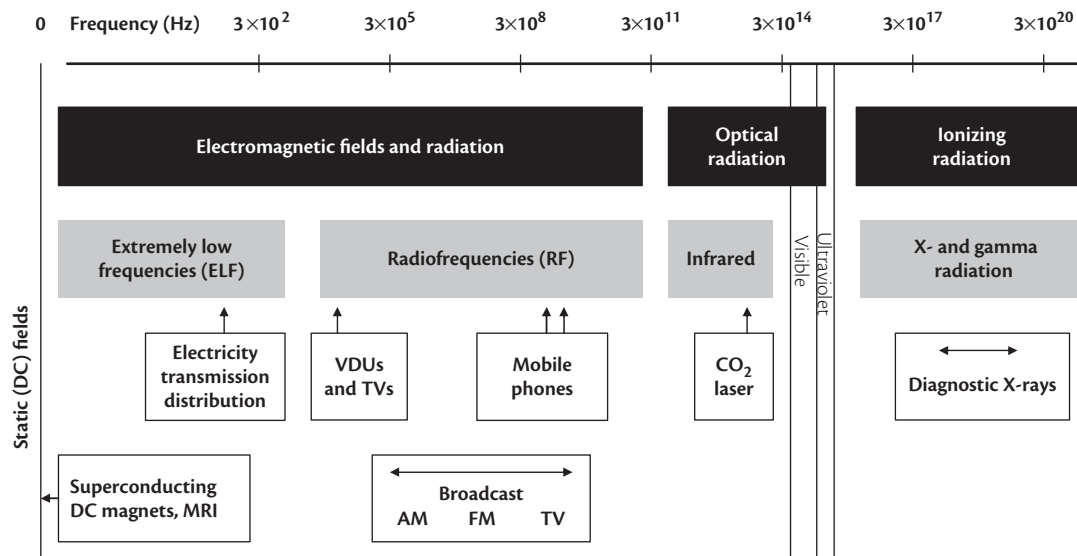

Fig. 7.2.1 Major sources of radiation and electromagnetic spectrum.

Laboratory studies of animals show aversive responses and field avoidance at 4 T or higher, probably vestibular in nature. Thresholds for motion-induced vertigo are estimated to be 1 T per second for greater than 1 second.

Cancer

The few epidemiological studies published to date leave a number of issues unresolved concerning the possibility of increased cancer risk from exposure to static magnetic fields. These studies have been carried out almost exclusively on workers exposed to static magnetic fields generated by equipment using large DC fields. Assessment of exposure has been poor, and the number of participants in the studies has been very small. Most of the studies were conducted in aluminium or other smelter plants. The limitations of these studies in providing useful information are supported by their lack of clear evidence for increased risk due to other, more established, carcinogenic factors present in some of these work environments: aluminium reduction creates coal tar, pitch volatiles, fluoride fumes, sulphur oxides, and carbon dioxide. Although some welders are exposed to relatively high static fields in some processes, they are also exposed to fumes and ELF and RF magnetic fields. Furthermore, most of the studies on welders do not provide enough information to determine the type of welding used, limiting the usefulness of these data in a review of potential health effects of static magnetic field exposure. Other work environments with a potential for high fields, for example, MRI technicians, have not been adequately evaluated, but have been identified as a high research priority by the World Health Organization (WHO 2006). In short: there is insufficient information for proper risk assessment of the impacts of static magnetic fields on cancer. Evidence from animal carcinogenesis studies is inconclusive, in the few studies that have been carried out (van Rongen et al. 2007).

Other outcomes

Even less information is available on other outcomes such as reproductive outcomes. One study examined fertility and pregnancy outcomes in female MRI operators, where the potential for exposure to relatively large static fields of up to approximately 1 T may have existed. The risk of miscarriage for pregnancies during MRI

work was slightly increased compared to work in other jobs and was considerably higher than the risk of homemakers (Evans et al. 1993), but the study was methodologically weak. Several indicators of reproductive health were studied in aluminium and metal workers with inconsistent results in a study with numerous methodological limitations. No adverse effects have been demonstrated in animal studies, but there are few good studies, especially with exposures in excess of 1 T (WHO 2006).

Policy and prevention (static fields)

Exposure to equipment generating large static electric fields is uncommon. Exposures to large static magnetic fields (up to several tens of mT) occur as a result of the industrial use of DC electric currents, for example, in welding and electrolytic processes, and less commonly in high-energy physics laboratories and experimental fusion reactors. Few countries have developed exposure guidance.

However, exposure may be becoming more common. With the advent of superconductor technology in the latter part of the twentieth century, it has been possible to develop large electromagnets capable of generating fields in excess of 1 T. Patient exposure to fields of 1–3 T during clinical MRI diagnostic procedures is now routine, and will increase in the future as technology develops. Most MRI use involves relatively short scans of less than 1 hour, and there are usually clear benefits to the person being scanned, hence the approach to guidance on exposure is different from that adopted for occupational and public exposure, because of the different risk/benefit ratio to those concerned.

The International Commission on Non-Ionizing Radiation Protection (ICNIRP) recommended a spatial peak magnetic field of 2 T for head and trunk, which can be raised to 8 T for limbs or in a controlled environment (ICNIRP 2009). For the general public, a recommendation that exposure should not exceed 400 mT is given. Special consideration should be given to patients, whose whole-body exposure should be limited to 4 T in normal mode, and go up to 8 T in a controlled mode. More caution is recommended above 8 T, which is considered experimental and should be accompanied by clinical monitoring. Further, to avoid vertigo and

nausea, patients should move or be moved slowly during the MRI procedures and in the presence of high fields.

Extremely low frequency

Sources and environmental levels

Extremely low-frequency electromagnetic fields (ELF EMF) are associated with all aspects of the production, transmission, and use of electricity. The fields are imperceptible to humans and are ubiquitously present in modern societies. ELF EMF are composed of two separate components, electric fields and magnetic fields. Electric fields are created by electric charges and are measured in volts/metre (V/m). Typical residential exposure levels are under 10 V/m. In the immediate vicinity of electric appliances, exposure levels can reach as high as several hundred V/m, whereas exposure levels immediately under high-tension power lines can reach several thousand V/m.

Average magnetic field exposures in the workplace have been found to be higher in electrical occupations which include power and telephone line workers, electricians, and electrical engineers, among others, than in other occupations such as office workers. Exposures range from 0.4 to 0.6 μT for electricians and electrical engineers to approximately 1 μT for power line workers and above 3 μT for welders, railway engine drivers, and textile workers. By contrast, typical residential exposure levels are around 0.1 μT . In the immediate vicinity of electric appliances that are in use, magnetic fields could be as high as several hundred μT but are usually only of short duration.

Health effects

Since the late 1970s, numerous epidemiological studies of varying quality have investigated possible health risks from residential and occupational exposure to both electric and magnetic fields.

Cancer

An association between higher-than-average magnetic field exposure levels and leukaemia risk is reported in most of the approximately 30 epidemiological studies investigating childhood leukaemia and ELF EMF. However, most of them are based on a small number of highly exposed cases and, thus, lack precision. A robust biological hypothesis to explain this association is lacking. In 2000, two independently conducted pooled analyses of previously published studies showed a statistically significant, approximately twofold increase in childhood leukaemia risk for average residential exposure levels above 0.3 or 0.4 μT , compared to the lowest exposure category of 0.1 μT or lower (Ahlbom et al. 2000; Greenland et al. 2000). More recently, Kheifets et al. (2010a) identified 14 studies published since the two previous 2000 pooled analyses, of which seven met their inclusion criteria. The odds ratios for exposure above 0.3 μT compared to lower than 0.1 μT was 1.44 (95 per cent confidence interval (CI): 0.88–2.36). Without the most influential study, from Brazil, which is suspected to be particularly prone to bias, the odds ratios increased and became similar to previous pooled analyses. Risk increases this small are notoriously hard to evaluate in epidemiology because it is usually difficult to achieve enough precision to distinguish a small risk from no risk. Such small effect estimates, compared to larger ones, are also more likely to result from inadvertent error, or bias, that can occur in epidemiological studies (Greenland and Kheifets 2006). Selection bias,

which can arise in the process used to select or enrol study participants, might explain some of the observed association (Mezei and Kheifets 2006). Given (1) the small associations observed in studies of magnetic fields and childhood leukaemia, (2) a limited understanding of causal risk factors for childhood leukaemia, (3) methodological difficulties in an assessment of a non-memorable and highly variable exposure, and (4) the potential for selection bias, a conclusive interpretation of these findings remains a challenge. The lack of a robust biophysical mechanism that would explain how environmental magnetic fields could cause cancer and a lack of support from laboratory investigations also indicates that the findings might be a result of study design and measurement issues rather than being truly causal. However, the remarkable consistency of epidemiological studies is difficult to dismiss, or explain away.

Kheifets et al. performed a similar pooled analysis for childhood brain tumours (2010b). In contrast to childhood leukaemia, there was little indication of an elevation in risk in the highest exposure category, and much less of a monotonic exposure–response relationship (with risk ratios below one in intermediate exposure categories). Results for other cancers, such as adult leukaemia and brain cancer (occupational exposures mostly) are less consistent than those for childhood leukaemia (Kheifets et al. 2008). For breast cancer a biological mechanism has been proposed but has not been confirmed in recent epidemiologic studies which strongly argue against an association (WHO 2007).

Other health outcomes

A number of additional health outcomes, particularly neurodegenerative disease, reproductive outcomes, and cardiovascular disease, have also been investigated in epidemiological studies. Motor neuron diseases and reproductive outcomes have not been sufficiently investigated, and studies that have been conducted are characterized by methodological difficulties. In a recent meta-analysis of occupational studies of exposure to ELF EMF and neurodegenerative disease, investigators found weak associations for proxies of occupational magnetic field exposures with Alzheimer's disease (AD) and motor neuron diseases (MND) (Vergara et al. 2013). MND risk was associated with electric occupations but not with magnetic fields, while AD risk was associated with estimated magnetic field levels. Disease misclassification, particularly for AD, and imprecise exposure assessment affected most studies. The epidemiological results are thus inconsistent and lack supportive laboratory evidence.

Epidemiological investigation of cardiovascular diseases has been motivated by biologically based hypotheses which stemmed from two independent lines of evidence: (1) magnetic fields were reported to reduce the normal heart rate variability in human experiments, and (2) several prospective cohort studies have suggested that reductions in some components of heart rate variability are associated with increased risk for heart disease, overall mortality rate in survivors of myocardial infarction, and sudden cardiovascular death. Thus, it was hypothesized that occupational exposure to magnetic fields increases the risk for cardiac arrhythmia-related conditions and acute myocardial infarction, but not chronic cardiovascular disease. Although an initial study appeared to support this hypothesis, recent larger and more rigorous studies have found no effects and have failed to confirm earlier findings, which suggest that ELF magnetic fields do not play a role in the development of cardiovascular diseases (Kheifets et al. 2007).

Policy and prevention

During the past decade, a number of national and international expert panels, including ones assembled by the United States National Institute of Environmental Health Sciences, the International Agency for Research on Cancer (IARC) and the WHO have reviewed the evidence on the potential relationship between exposure to ELF EMF and various adverse health outcomes (National Institute of Environmental Health Sciences 1999; IARC 2002; WHO 2007). Evaluations by these expert panels generally agree that short-term, adverse effects do not occur at exposures to magnetic fields below 100 μ T. Current guidelines (recently revised) are based on induced internal electric fields and use a threshold for an induction of magnetic phosphines. For general public exposure, the reference levels for power frequency (50 Hz) electric and magnetic fields are of the order of 5 kV/m and 200 μ T, respectively. These values are well above levels encountered in most environments.

Based on these intensive reviews IARC and WHO classified ELF magnetic (but not electric) fields as a 'possible human carcinogen', or a Group 2B carcinogen. This classification was based both on epidemiological evidence showing a consistent association between exposure to ELF magnetic fields and childhood leukaemia even though laboratory studies in animals and cells do not support an association between exposure to ELF magnetic fields and cancer.

Several risk characterization attempts have indicated that the public health impact of residential magnetic fields on childhood leukaemia is likely to be limited (Kheifets et al. 2006). Positing sensitivity and bias models for methodological problems in the epidemiologic studies and accounting for uncertainties regarding field levels that may have effects, suggest that, in light of the available data, both no public health impact and a large impact remain possibilities (Greenland and Kheifets 2006).

The combination of widespread exposures, established biological effects from acute, high-level exposures, and the possibility of leukaemia in children from low-level, chronic exposures have made it necessary but difficult to develop consistent public health policies. In view of these uncertainties, it might be advisable to adopt general no- and low-cost measures to reduce exposure (WHO 2007).

Intermediate frequency

Intermediate frequency (IF) exposures occur in the range 300 Hz to 10 MHz, partially encompassing frequencies also assigned to very low-frequency (VLF; 0.3–30 kHz) and high (3–30 MHz) ranges.

Because few biological studies of exposures to intermediate frequencies have been conducted, exposure guidelines have largely been extrapolated from the encompassing ELF (at the low end) and RF (at the high end) limits.

Sources and environmental levels

Intermediate frequency exposures are common from occupational appliances such as induction heaters (used in the heating of metals prior to manipulation) and plasma heaters. Smaller exposures occur from induction heating elements in residential cooking appliances. Television, radio, and other communications transmitters can emit IF, but they are discussed in the section on RF, which constitutes the much more common wavelengths of exposure from such sources. Indirect exposures from medical equipment (e.g. MRI machines and magnetic bone stimulators where pulses may drop to IF levels) may occur rarely. Direct exposures to IF may also occur from surgical

equipment used for tissue cutting and cauterizing. Common exposures to IF occur in proximity to devices that read magnetic cards or buttons for identification purposes (Polichetti and Vacchia 1996), and similarly, from antitheft devices that read magnetic identification tags. Very small exposures are obtained from television screens (and CRT computer monitors). Use of antitheft technologies, device tagging and identification is increasing rapidly, exposures immediately beside RFID reader antennas can be locally higher, and simultaneous exposures can come from a variety of IF sources, locations of which may be unknown (ICNIRP 2008).

Health effects

Since exposure level and proximity to the source together determine the IF levels in tissue, knowledge of both is important in determining the biological effects of IF exposure levels in humans.

Biological effects in humans can be either thermal, when frequency is sufficient to induce a heating response, or non-thermal (i.e. cell membrane excitation or electroporation), when frequency does not induce a heating response.

Studies of the impact of IF on human health, particularly with exposure from new technologies, are currently lacking.

Policy and prevention

Because of the lack of data, currently there are no specific recommendations for limiting exposure to IF, other than those extrapolated from EMF at extremes of the IF range (ELF and RF). As use of IF fields and subsequent exposure to the population is increasing, there is an increased interest in characterizing exposure and health effects in the IF range. GERoNiMO is: <http://www.crealradiation.com/index.php/en/geronimo-home>.

Radiofrequency radiation

Sources and environmental levels

With rapid advances in EMF technologies and communications, people are increasingly exposed to frequencies in the RF range. RF fields are produced by radio and TV broadcasts, mobile phone base stations, and other communication infrastructure. The most prevalent exposure is to handheld mobile telephones. This technology typically uses frequencies from 450 to 2500 MHz, although new technology has broadened this band. Other sources of exposure to the general population are radio and television transmitters which operate at between 200 kHz and 900 MHz. Radio and TV signals are broadcast to a large area from comparatively few sites (Neubauer et al. 2007). Compared to radio and TV transmitters, mobile phone base stations cover a smaller area, and produce much lower emissions, but are vastly more common in many countries. Residential exposures also come from wireless monitors used in children's cribs, cordless phones, and wi-fi (wireless Internet connections) commonly used at home and in schools. Occupational exposures include RF PVC welding machines, plasma etchers, and military and civil radar systems. All operate at different frequencies.

Handheld mobile phones available since the late 1980s became widely used by the general population only in the late 1990s. Currently there are more than 5 billion mobile phone users worldwide, with a penetration in some countries reaching 120 per cent (i.e. many people have more than one phone). Use of mobile phones has changed markedly over recent years, concomitant with the development of new technologies (e.g. 2G to 3G, power control,

handover management, and novel uses of smartphones). Phones operating under 2G and 3G can have significantly different output power; 3G is thought to be around 1 per cent of the power emitted by a phone operating under 2G. In addition, modes of mobile phone use are constantly changing as texting, web-surfing, playing games, and listening to music on mobile phones are becoming more and more common. Exposure from mobile phones is concentrated closest to the handset and the antenna. Absorption of RF from mobiles is localized and depends on the position of the phone during use. This represents a very important determinant of exposure: only calls made with the mobile phone close to the head result in absorption of RF energy inside the head.

Exposures from mobile phone base stations are several orders of magnitude lower than from the phones. For whole-body exposure, mobile phone base stations can be the largest individual source of RF, but other sources such as radio or TV transmitters can result in comparable exposures depending on where the measurements are taken. For RF sources other than mobile phones, typical power densities outdoors would be 0.01–1 mW/m², but could be orders of magnitude higher (i.e. 100 mW/m² and above). Indoor levels are often lower than outdoor exposures by orders of magnitude; for example, in Europe, a median indoor power density of 0.005 mW m⁻² has been reported. Note that the exposure from base stations differs from that of mobile phones; base stations expose the whole body, but the exposure duration is considerably longer. Perhaps more importantly, base station exposure has been a subject of much concern to the public because it is not under the control of the public and its presence is not perceived to be of direct individual benefit.

Population exposure to RF fields has been less completely characterized than exposures to ELF fields. This is due to: (1) technical challenges, (2) the rapid evolution of RF-related technology (frequency, coding schemes), and (3) changing patterns of use (duration of calls, text messaging, web surfing, etc.).

Health effects

Since RF radiation induces heating in body tissues and imposes a heat load on the whole body, prevention of excessive heating serves as a basis for most international guidelines for human exposure. Studies of the interaction of RF with tissue in the range used for mobile phones have led to the proposal of many different non-thermal mechanisms for RF interaction. Generally, it is thought that non-thermal interactions are unlikely to be biologically significant at the RF levels below guidance values, but much of the ongoing research is directed towards non-thermal mechanisms.

Cancer

Epidemiological studies of health effects related to RF exposure from mobile phones have primarily focused on cancer, especially brain tumours. While over the past 10 years there have been a large number of studies focusing on mobile phones, studies with long-term exposure with sufficient latency are still limited. Currently it is only possible to evaluate short- to medium-term effects of mobile phone exposure; the majority of studies have found no effects on either brain or parotid gland tumour risk (Swerdlow et al. 2011). Exposure assessment remains problematic: substantial random error has been shown for even short-term recall of mobile phone use; and information bias appears to affect at least the reporting of the side of the head where the phone is commonly used. Also,

some studies may be compromised by a non-representative control group, caused by an increased participation of mobile phone users. Results for acoustic neuroma are more suggestive albeit inconsistent (Swerdlow et al. 2011). Recently, a few studies have examined other cancers, such as leukaemia, non-Hodgkin's lymphoma, and uveal and testicular cancers. Results are unremarkable, but subject to the same limitations as brain tumour studies. So far only one study has examined the possible association between brain tumours and use of mobile phones in children (Aydin et al. 2012). Small and imprecise risks were reported in the high exposure categories, which became more pronounced in a subgroup of about one-third of the subjects for whom objective operator data was available. However, due to methodological limitations, some internal inconsistencies, and most importantly, lack of increases in the brain tumour rates for children in the registry, the authors consider their data to argue against causality. Clearly, more studies of children are needed.

A few studies have assessed cancer risk in relation to radio and TV transmitters (Ahlbom et al. 2004). Often driven by a previously identified cancer cluster, these analyses are based simply on distance from the source and often include an extremely small number of cases. It is therefore not surprising that such studies have been uninformative. Four recent case-control studies of cancer risk related to mobile phone base stations (Ha et al. 2007; Merzenich et al. 2008; Elliott et al. 2010; Li et al. 2012) have employed improved methods both in terms of design and exposure assessment. While reporting some positive associations for disease and exposure subgroups, overall these studies provide no consistent evidence of association between exposure from base stations and other transmitters and risk of childhood cancer. However, numerous methodological limitations remain, including the inability to detect small increases in risk.

Although occupational studies have been performed over a longer time period, we are only beginning to measure and learn about RF exposures in various occupations, and the exposure may not always be relevant for an assessment of effects of mobile phone frequencies. Although some increased risks have been found in certain studies, there is no consistent evidence of risk increases for any cancer sites. The studies have several methodological weaknesses: (1) none of the studies have made measurements of the actual RF exposure for the subjects included, (2) exposure classification has often been based on the job title alone, and (3) no or only limited control of confounding has been made (Ahlbom et al. 2004).

All of the studies have reported null results for carcinogenicity in normal animals at exposure levels compatible with mobile phones; however, co-carcinogenicity studies have been suggestive (IARC 2012). As a result, the IARC classified RF as possibly carcinogenic to humans based on limited evidence in humans (from studies of glioma and acoustic neuroma in relation to mobile phones) and limited evidence in animals (based on co-carcinogenicity studies).

Other outcomes

It is well established in animal studies that hyperthermia during pregnancy can cause embryonic death, abortion, growth retardation, and developmental defects; development of the central nervous system is especially susceptible. Serious health effects of hyperthermia in humans are associated only with greatly elevated body temperatures (> 40°C), and such temperature rises are well above those generated by the maximum allowable level for public RF exposure.

Numerous studies have evaluated developmental effects of RF fields on mammals, birds, and other non-mammalian species (Heynick and Merritt 2003; Independent Advisory Group on Non-Ionizing Radiation 2003). These studies have shown that RF fields are teratogenic at exposure levels that are high enough to cause significant increases in temperature. There is no consistent evidence of effects at non-thermal exposure levels, although a few studies have evaluated possible effects on postnatal development using sensitive end points, such as behavioural effects.

Several studies of occupational RF exposure, primarily to physiotherapists, have reported an increased risk of congenital malformations, but no specific type of malformation has been consistently reported, and there is a potential for recall bias in these studies (Larsen 1991). Exposure to RF during sensitive periods of development in early life may lead to lasting effects on health (Kheifets et al. 2005). No association was found between mobile phone use during pregnancy and early neurodevelopment in very young children in two studies (Vrijheid et al. 2010; Divan et al. 2011). A Danish study has raised the hypothesis that pregnancy and childhood exposure to mobile phones may result in common childhood behavioural problems (Divan et al. 2008). Behavioural problems related to cell phone use in children stand out as the only association independently confirmed in several studies (Abramson et al. 2009; Thomas et al. 2010; Divan et al. 2012). Prospective evaluations of this association in large cohorts are needed.

Possible health effects based in part on anecdotal reports of numerous symptoms such as headaches and sleep disturbance from continuous whole-body RF exposure from base stations is an area of major public concern. Because of numerous methodological shortcomings, data regarding effects of such RF exposure on symptoms are inadequate for assessment at present.

Policy and prevention

Guidance on exposure for the general public is intended to restrict local tissue temperature rises to acceptable levels and currently is set to 0.08 Wkg^{-1} , for the whole body, and 2 Wkg^{-1} , for the head. Mobile telephones have only been in widespread use for a relatively short time and therefore, the possibility remains that long-term RF exposures from mobile telephony can have adverse health effects. More importantly, many of the health outcomes are yet to be studied and research on potential detrimental effects on children is particularly sparse.

The need for public health policy coupled with the paucity of data, particularly for children regarding the long-term health effects of mobile phone use, suggests that low-cost precautionary measures are appropriate. Mobile phone use is increasingly common among school children, and teenagers may be among the heaviest mobile phone users today with some exposures close to guideline limits (Kheifets et al. 2010c). Exposure can be reduced by users restricting the length of their calls, or by using 'hands-free' devices to keep mobile phones away from the head and body.

Infrared radiation

Sources and environmental levels

Wavelengths between 780 nm and 1 mm are classified as IR. The IR spectrum is conventionally broken down into three separate categories: IR 'A' (780nm–1.4 μm); IR 'B' (1.4–3 μm); and far-IR 'C' (3 μm –1mm). Besides solar radiation and fire as common natural

sources, artificial sources of IR include a variety of therapeutic and domestic applications such as heating devices, lights, 'infrared saunas', and industrial sources related to heat production such as in steel/iron industries. Lasers comprise a special group that emit IR radiation over one or more extremely narrow wavelength bands, not covered in detail here.

Health effects

IR penetrates human skin and ocular tissues, namely the cornea, lens, and retina, to varying depths depending on wavelength, ranging from several millimetres (IR-A) to only superficial absorption (IR-C). Humans have protective aversion responses to thermal pain and to the bright light/visible radiation that is often also present, so that potentially hazardous exposure can be avoided. When harmful effects of IR in humans do occur, most studies suggest that the main mechanism of action is thermal injury, with little evidence of photochemical or other biological interactions.

Harmful effects

Harmful effects of any episode of hyperthermia of the skin depend on the intensity and the duration of the IR exposure (Moritz et al. 1947). When the temperature of the skin is held at 44°C , around 6 hours is required before irreversible skin damage is sustained, while at surface temperatures of 70°C or higher, less than 1 second is required to cause epidermal necrosis (Moritz et al. 1947). In industrial settings, whole-body heat stress tends to limit the duration of exposure to IR radiation, keeping it under the threshold for thermal damage to the skin, and so only very brief exposures to very high irradiances pose a thermal hazard. Chronic IR exposure of the skin without burning (such as repeatedly sitting with exposed skin close to open fires—common in the past) can cause a distinctive red-brown mottling of the skin known as erythema ab igne. IR is not considered relevant in the initiation of skin cancer although it has been hypothesized that IR might accelerate UV-induced skin carcinogenesis (Edwards et al. 1999), possibly by reducing DNA repair ability (Dewhirst et al. 2003), or by triggering damage by reactive oxygen species, but supportive evidence is scant.

The main detrimental effect of high IR exposure is to the eye due to the sensitivity of the cornea, iris, lens, and retina to thermal damage, though damage thresholds for these tissues vary greatly depending on the precise wavelength and exposure duration. For example, with laser irradiation at 1.315 μm , the cornea is the most sensitive of the tissues to continuous wave exposure. The retina, lens, and iris are sensitive to short exposure durations of approximately 0.1–1.0 seconds, and the retina is the eye tissue most sensitive to damage by sub-millisecond laser pulses (Zuclich et al. 2007). When incident IR radiation is absorbed by the cornea it is converted into heat which is conducted to the lens with marked decreases in lens proteins whose aggregation is thought to lead to the lens opacity of cataract (Aly and Mohamed 2011). There is considerable evidence of IR-induced cataract in industries with extremely high exposures (e.g. glass workers (Lydahl and Philipson 1984) and iron and steel workers (Wallace et al. 1971)). Most non-industrial exposures to IR appear insufficient to cause cataract or other eye damage however.

Workers exposed to high levels of IR contend with whole-body hyperthermic effects (rise in body temperature causing heat-stress) which are similar to those in any industry involving physical activity in warm environments. The same is likely true of risks of excessive exposure to far-IR saunas or warming cabins. Thus, the

exposure limits in these situations will rely mainly on ensuring that safe body temperatures are maintained.

In summary, there have been relatively few studies of the health effects of IR, but current evidence suggests that harmful effects are few and due to acute high-intensity exposure or to chronic exposure, causing ocular damage and heat-related illness in certain situations.

Beneficial effects

A single review of the health benefits of far-IR saunas has been carried out, restricted to evidence from randomized controlled trials, non-randomized trials, and cohort studies (Beever 2009). Far-IR (around 10 μm wavelength) saunas are popular because they operate at lower temperatures than traditional saunas and promote greater sweating since skin penetration by IR is greater than by hot air. The review found moderate, limited evidence to support far-IR saunas in normalizing blood pressure and treating congestive heart failure, very limited evidence supporting decrease in chronic pain, and only weak evidence for benefit in chronic fatigue syndrome and obesity (Beever 2009).

Policy and prevention

There are various international standards for limiting exposure to IR that are provided separately for IR-A, B, and sometimes C (ICNIRP 2006). These limits, based on combinations of wavelength and time of exposure, are most appropriate for industrial applications where exposures are extreme and measurable. The heat-generating effects of IR tend to be avoided when humans react to minimise exposure before thermal injury to the skin occurs. This is not true for exposures causing cataract, so specific recommendations exist for wearing protective eye coverings and limiting exposure to IR. Again this applies largely to occupational settings with extreme exposures and assumes that any exposure of the eye to IR is potentially harmful.

There are currently no recommendations for limiting or avoiding exposures to IR in saunas and other recreational settings other than to limit exposure to avoid heat-related illness.

Ultraviolet radiation

Sources and environmental levels

Ultraviolet (UV) radiation is categorized as UVA (400–320 nm), UVB (320–280 nm), and UVC (280–250 nm), and the sun is the natural source. All UVC and much of the UVB emitted by the sun are absorbed by the earth's atmosphere such that the midday sun comprises about 95 per cent UVA and 5 per cent UVB, although in recent decades depletion of ozone in the stratosphere by man-made chlorofluorocarbons has resulted in greater levels of UVB on the earth's surface in some temperate and arctic regions. Solar UVB levels increase with decreasing latitude and increasing altitude and are highest in the summer and in the middle hours of the day; levels of ambient UVA mostly parallel UVB levels. Light cloud cover prevents about 50 per cent of solar UV energy from reaching the earth's surface (Diffey 1991), while very heavy cloud cover can virtually eliminate UV radiation. Reflectance from light-coloured surfaces such as concrete, snow, and to a lesser degree, water, increases terrestrial UVB.

There are a variety of sources of artificial UV found in occupational and medical settings and these include mercury vapour lamps, arc-welding, commercial germicidal UV lamps, and dental

polymerizing equipment. In addition, over the last two decades the sunbed industry has emerged as a prevalent source of community UV exposure, sought after by fair-skinned people, particularly adolescents and young adults, seeking to acquire a tan by artificial means (Olsen and Green 2012).

Health effects

The penetration of human tissues by UV radiation and the ensuing health effects are not only wavelength-dependent with longer UVA wavelengths penetrating human tissues more deeply than UVB, but also age dependent. The structure of juvenile skin may result in increased UV dosage and more damage to target cells than in adult skin, with increased childhood susceptibility to long-term carcinogenic effects (Green et al. 2011); for example, in the juvenile eye, the crystalline lens allows UV transmission to the retina and choroid, whereas after around 25 years of age the adult lens and cornea filter almost all UV (Lerman 1984).

Harmful effects

Acute exposure to UVB causes inflammation of the skin (sunburn) and eye (photokeratitis of the cornea) and immunosuppression (Young 2006). Chronic UV exposure of the skin causes photoaging, benign keratinocytic skin tumours (actinic keratoses), and skin cancer (basal cell and squamous cell carcinomas (BCC and SCC) and melanoma) (IARC 2012). Skin colour determines sensitivity to the acute and chronic effects of UV radiation on the skin, with white Caucasians bearing most of the burden of harmful effects compared with those with black or olive skin. Chronic UV exposure of the eye causes a range of degenerative effects, for example, pterygium, cataract, macular degeneration, as well as cancer (SCC and ocular melanoma) regardless of skin and eye colour.

The carcinogenic effects of solar UV radiation derive from the combined action of UVB and UVA: direct damage by UVB and to a less extent by UVA to DNA through cyclobutane pyrimidine dimer formation as well as the indirect oxidative damage induced by UVA, modulated by the efficiency of DNA repair pathways such as nucleotide excision repair (Ikehata and Ono 2007). UV radiation also suppresses the immune system by inducing immunosuppressive mediators and by interfering with immune responses of antigen-presenting cells (Halliday and Rana 2008).

A multitude of epidemiological studies support the causation of cancers of the skin by solar UV radiation in white populations (IARC 2012), ranging from descriptive studies showing positive associations with birth and/or residence at low latitudes and rare occurrence at non-sun exposed body sites, to analytic studies indicating that biological indicators of excessive sun exposure, namely multiple sunburns (throughout life, but especially in childhood) and actinic keratoses, are significant risk factors (Whiteman et al. 2001; Fears et al. 2002; Chang et al. 2009). Further, there is now evidence from randomized controlled trials that regular application of a broad-spectrum sunscreen to the skin to filter at least 95 per cent of UVB and a proportion of UVA, protects against actinic keratoses, SCC, and melanoma (Thompson et al. 1993; Green et al. 1999, 2011). Convincing evidence is now also available from cohort studies and meta-analyses that the use of tanning beds increases the risks of all three major skin cancers—BCC, SCC, and melanoma—particularly if exposure occurs during the first three decades of life (IARC 2007; Boniol et al. 2012; Olsen and Green 2012; Wehner et al. 2012; Zhang et al. 2012).

Beneficial effects

Besides the modest photoprotection of pale skin against further UV-induced skin damage that is provided by a suntan, UV exposure enhances vitamin D synthesis which is essential to bone health. Conclusive evidence of benefit of UV radiation beyond bone health, mediated through vitamin D or otherwise, is not presently available, however (National Research Council of the National Academies 2011; Thacher et al. 2011; Allinson et al. 2012). When a systematic review of vitamin D and cancer was performed by the IARC in 2008, benefits were inconclusive and did not outweigh the harms (IARC 2008), and later systematic reviews have been consistent with this (Gandini et al. 2011).

Policy and prevention

Limiting exposure to solar UV

The Global Solar UV Index (UVI) is a unitless quantity estimated on a daily basis that describes the maximum intensity of solar UV radiation received on the earth's surface (Allinson et al. 2012). Originally introduced by the WHO, the United Nations Environment Programme, the World Meteorological Organization, and the International Commission for Non-Ionizing Radiation Protection (ICNIRP) as a measure to monitor changes in terrestrial UV irradiation (caused, for example, by ozone depletion), the UVI has had its utility since expanded to serve as a public awareness tool about the amount of harmful UV radiation present at a specified location (WHO 2002). Guidance about appropriate sun protection measures is also provided in line with standard recommendations of cancer control agencies worldwide on how best to avoid solar UV exposure in order to facilitate the primary prevention of skin cancer. These are: limit exposure during midday hours; seek shade; wear protective clothing including a broad-brimmed hat to protect the eyes, face, and neck; protect the eyes further with wrap-around sunglasses with side panels; use and reapply broad-spectrum sunscreen of sun protection factor (SPF) 15+ liberally; and protect babies and young children (WHO 2002). The specific use of at least sunscreen is advocated as an adjunct to physical protection measures (shade, clothing cover) and sunscreen should be reapplied after sweating, swimming, and long periods in the sun. Despite much evidence from ecological and observational studies about sun exposure, vitamin D, and human health outcomes, currently there is an absence of evidence from randomized controlled trials about their quantitative relationships, and thus, there is as yet no established basis on which to include vitamin D considerations in sun protection recommendations (Allinson et al. 2012).

Limiting exposure to sunbeds

Many countries have enacted legislation to more tightly regulate the sunbed industry and limit people's exposure to this source of UV radiation. Sunbeds are banned in Brazil, and legislation prohibiting use by those under 18 is in place in France, Spain, Portugal, Germany, Austria, Belgium, England, Wales, Northern Ireland, and Scotland, and parts of Australia, Canada, and the United States (Pawlak et al. 2012). These regulations need to be reinforced by warnings from health professionals and educators about the risks of indoor tanning, so that young people in particular are aware that their use of sunbeds for short-term cosmetic tanning materially raises their skin cancer risk (Olsen and Green 2012).

Limiting occupational exposures

The ICNIRP recommends upper limits of exposure to UV in occupational settings, outdoor and indoor, to protect both the skin and the eyes of workers (ICNIRP 2004). It is recognized that the risks of UV exposure of the skin differ greatly depending on skin colour: skin protection must be emphasized for white-skinned people, while higher average threshold exposure is allowed for Asian and black skin types. Eye protection against UV is emphasized for all skin types.

For the outdoor worker, exposure of the skin depends upon the work tasks and posture, exposure duration, the particular environment, time of day, and season, and all of these factors need to be taken into account in establishing appropriate control measures. Under most situations, ocular UV exposure does not exceed the limits for even long exposure duration unless in environmental conditions where ground reflectance is unusually high (ICNIRP 2010). Standard protective clothing and headwear can be complemented by application of broad-spectrum sunscreen, while UV protective goggles can effectively reduce ocular UV exposure from high-reflectance surfaces like snow. For indoor workers' exposure to artificial sources such as UVC-emitting lamps for sterilizing work areas in hospitals, the food industry, and laboratories, or UV lasers, safety precautions include engineering (structural) and administrative controls and personal protective equipment and training. Educating individual workers about the risks of excessive UV exposure is also of paramount importance (ICNIRP 2010).

Ionizing radiation

Ionizing radiation consists of high-frequency electromagnetic radiation—X-rays and gamma-rays—or of subatomic particles such as alpha-particles (^4He nuclei), beta-particles (electrons), neutrons, protons, pions, and muons. For radiation to be ionizing it must have high enough energy to eject electrons from atoms or molecules, thus creating electrically charged ions. Electrically charged particles (e.g. alpha- and beta-particles) are directly ionizing, whereas electrically neutral particles (e.g. gamma-rays and neutrons) are ionizing because they produce charged particles on interacting with matter. The energy deposited in matter by ionizing radiation is measured in gray (Gy), 1 Gy being 1 J/kg, which is the absorbed dose of radiation (National Research Council of the National Academies 2006; International Commission on Radiological Protection (ICRP) 2007; United Nations Scientific Committee on the Effects of Atomic Radiation 2008, 2010).

The amount of energy transferred by particles per unit track length when passing through matter is called the linear energy transfer (LET) of the radiation. For example gamma- and X-rays, electrons and muons are sparsely ionizing—low-LET—radiations because relatively few ionization events occur along their paths. On the other hand, alpha-particles, neutrons, and accelerated heavy charged nuclei (e.g. ^{12}C) generated by synchrotrons are termed high-LET radiations because they transfer a relatively large amount of energy per unit track length, producing a high density of ionizations. Measurement units commonly used are defined and listed in Table 7.2.1 (ICRP 2007).

For the purposes of radiological protection, in the context of low doses (< 100 mGy of low-LET radiation) or low dose-rates (< 0.1 mGy/min, as an hourly average, of low-LET radiation), the absorbed dose is weighted by the different ionization capabilities of

Table 7.2.1 Quantities and dose units of ionizing radiation

Quantity dose	Unit	Definition
Absorbed dose	gray (Gy)	Energy deposited in matter (= 1 J/kg)
	Rad (obsolete unit)	1 rad = 100 erg/g = 0.01 Gy = 1 cGy
Equivalent dose	sievert (Sv)	Absorbed dose multiplied by the radiation weighting factor, w_R , for the particular type of radiation
	Rem (obsolete unit)	1 rem = 0.01 Sv = 1 cSv
Effective dose	sievert (Sv)	Sum of equivalent doses, each multiplied by the tissue weighting factor, w_T , for the particular tissue irradiated
Collective effective dose	Person-Sv	Sum of the individual effective doses for a population
Committed effective dose	sievert (Sv)	Cumulative effective dose to be received over a given period from a given intake of radioactive material
Radioactivity	becquerel (Bq)	One radioactive disintegration per second
	Curie (Ci) (obsolete unit)	37 billion disintegrations per second (= 37 GBq)

the various types of radiation and by the different radiosensitivities of the various human tissues, reflecting the overall health detriment posed by such exposures. The equivalent dose is given by the sum of the absorbed doses (averaged over a tissue) each multiplied by the radiation weighting factor for the particular types of radiation involved, and the effective dose is the sum of the equivalent doses received by different tissues with each equivalent dose weighted by

the tissue weighting factor—both equivalent and effective doses are measured in sievert (Sv). For low-level exposure, the effective dose gives the same overall risk of an adverse health effect as a whole-body dose of gamma radiation. It is used in radiological protection when different organs/tissues receive different doses, possibly from radiations with different radiation weighting factors (ICRP 2007).

Sources and environmental levels

Exposure to natural background radiation is ubiquitous. Additional exposure occurs from anthropogenic sources, mainly for the purposes of medical diagnosis. Overall, the world-averaged individual effective dose from naturally occurring sources is about 2.4 mSv/year, with a typical range of 1.0 to 13 mSv/year (United Nations Scientific Committee on the Effects of Atomic Radiation 2010). This represents about 80 per cent of the global average individual effective dose, the approximately 0.6 mSv/year received from artificial sources being dominated by medical exposures (United Nations Scientific Committee on the Effects of Atomic Radiation 2010). The different sources contribute the fractional amounts as summarized in Fig. 7.2.2. The rapid advance in radiodiagnostic technology (such as computed tomography (CT) scanning) has led to a comparatively large increase in doses from medical sources in developed countries (United Nations Scientific Committee on the Effects of Atomic Radiation 2010).

Naturally occurring sources

In addition to external sources of radiation, such as cosmic-rays originating from outside the Earth and terrestrial gamma-rays from naturally occurring radioactive materials in the environment, radionuclides are inhaled or ingested, irradiating the body from within, and the inhalation of the radioisotopes of radon and their radioactive decay products contributes on average more than 50 per cent of the effective dose from natural sources. Radon-222 is the main source of radon exposure and is produced by the decay of radium-226, which is a component of the radioactive decay chain of naturally occurring uranium-238; rarer radon-220 is part of the decay chain of naturally occurring thorium-232. When radon is inhaled the dose is largely from alpha-particles to the bronchial

**Fig. 7.2.2** Worldwide average annual individual effective dose (mSv).

epithelium, with a consequent risk of lung cancer. The ingestion of naturally occurring radionuclides is mainly through the presence of the decay products of uranium-238 and thorium-232, and of long-lived radionuclides such as potassium-40, in food and drink. When cosmic-rays strike the upper atmosphere, radionuclides are formed, mainly tritium (hydrogen-3) and carbon-14, and these enter the body largely through the consumption of food and drink.

There are important variations in the natural background dose depending on factors such as the nature of rock and soils, building materials, and altitude. There exist on Earth high natural background radiation areas where annual effective doses can exceed 10 mSv and even 100 mSv (77). These elevated levels may be due to gamma radiation, such as from the monazite sands of the coast of Kerala in India, but mainly they are due to gaseous radon entering buildings and producing high concentrations in air. Radon concentrations in some houses in the most affected areas of the world are sufficiently raised that remediation measures are necessary to reduce the consequent risk of lung cancer to acceptable levels. Cosmic radiation levels are increased at high altitudes due to decreased shielding by the atmosphere—air travel therefore raises the dose received from cosmic-rays, but with the exception of frequent travellers, this forms a relatively small increase in the overall dose from natural sources of radiation (Table 7.2.2).

Man-made radiation sources

The main man-made global contribution to environmental exposure has come from radioactive fallout from the testing of nuclear weapons in the atmosphere, mainly during the late 1950s and early

1960s. The world average annual effective dose reached a peak of 0.11 mSv in 1963, and since then it has decreased to about 0.005 mSv in 2000, most of this dose now coming from carbon-14 (United Nations Scientific Committee on the Effects of Atomic Radiation 2010). Other contributions are from the generation of electricity from nuclear energy and the production of nuclear weapons, and also from naturally occurring radionuclides in the discharges from fossil-fuelled power stations and other industrial plants, such as phosphate processing factories. Doses to members of the public from these exposures are now generally low at around 1 µSv. Doses to workers in the nuclear industry and in other occupations (e.g. industrial radiographers) have fallen over the years with improved radiological protection measures. The world-wide average annual dose in the nuclear industry is now about 1 mSv (Table 7.2.2). Modern technological advances have led to other sources of exposure, such as smoke detectors and security scanners, although the doses received from these are almost always minute.

Some potential sources of exposure have raised public concern, such as lost medical or industrial radiation sources, deliberate contamination of items such as foodstuffs with radioactive materials, or 'dirty bombs'. 'Dirty bombs' (a type of 'radiological dispersion device') spread radioactive materials by using conventional explosives (Amaldi and Kraft 2006), but it is difficult to assess just how dangerous these terrorist weapons would be in terms of radiological effects, and it is likely that the greatest impact would be psychological as a result of fear and panic.

Exposure from medical procedures

Modern diagnostic radiography assures earlier, more precise diagnosis and monitoring the progression of a large number of diseases. Screening procedures (such as mammography) are beneficial for specific populations who are at a higher risk from certain diseases. Diagnostic radiography using conventional X-ray examination, CT scanning, and positron emission tomography (PET) have significantly improved the staging and accuracy of diagnosis. In addition, a number of interventional radiologically driven procedures (such as angioplasty) introduced in the last 10–20 years, contribute significantly to the effectiveness of treatment of serious diseases of the cardiovascular and central nervous systems and other organs. Such technological improvements can be critically important in effecting cures, but involve relatively high exposure, and therefore should be used with care.

In recent years the use of nuclear medicine and in particular CT scanning has increased to a marked extent in economically developed countries. This increase is illustrated by the average annual effective dose to members of the population of the United States from medical procedures (mainly from diagnostic exposures), which was 0.53 mSv in the early 1980s, but had risen to 3.0 mSv in 2006, a level that is comparable to the average annual effective dose received from natural sources. The doses received from medical procedures are dependent on economic development: world-averaged individual dose from medical exposures during 1997–2007 was 0.62 mSv/year, but in countries with advanced healthcare systems it was 1.92 mSv/year (United Nations Scientific Committee on the Effects of Atomic Radiation 2010). The number of procedures carried out in the United States during 2006 in each category of diagnostic and interventional procedures, together with the average effective dose received per procedure, is given in Table 7.2.3 (National Council on Radiation Protection and Measurements 2009).

Table 7.2.2 Global occupational radiation exposures

Source of exposure	Average annual effective dose (mSv)	Number of monitored workers worldwide (thousands)
Man-made sources^a		
Nuclear fuel cycle (including uranium mining)	1.0	660
Industrial uses of radiation	0.3	869
Military activities	0.1	331
Medical uses of radiation	0.5	7440
Miscellaneous	0.1	565
Total from man-made sources	0.4	9865
Enhanced natural sources^b		
Aircrew	3.0	300
Mining (other than coal)	3.0	4600
Coal mining	2.4	6900
Other workplaces	4.8	1250
Total from natural sources	2.9	13,050

^a 2000–2002.

^b 1995–2002.

Radiation therapy is based on the ability of ionizing radiation to kill cells, and radiation can be targeted at a particular group of cells, such as cancerous cells. Radiotherapy saves many lives every year, and in the case of palliative treatment, substantially reduces suffering. There are also some non-malignant diseases whose treatment by radiation is also a method of choice. Most of the side effects of conventional radiotherapy are predictable and expected, arising from the unintentional irradiation of cells outside the target tissues, and one of the aims of modern intensity-modulated radiation therapy is to reduce the side effects to a minimum by sparing normal tissues (Hall 2006). However, radiotherapy inevitably leads to some degree of irradiation of healthy tissues and to some consequent risk of adverse health effects arising from this exposure. This is particularly relevant for deeply seated tumours, tumours closely located to critical organs, and paediatric tumours. One newly emerging method is the use of charged particles (e.g. protons and ^{12}C ions), with their positive physical and radiobiological properties, which allows highly conformal treatment of various kinds of tumours while delivering minimal doses to large volumes of surrounding healthy tissues. This means that they can cause severe damage to the DNA in cancer cells while sparing both traversed and deeper healthy tissue. This characteristic also enables them to be used for a more accurate irradiation of the tumour (Rosen 2001).

Recommendations for medical exposure

Medical exposures are intended to provide a direct benefit to the exposed individual. If the practice is justified and the protection optimized, the dose in the patient will be as low as is compatible with the medical purposes. Therefore dose limits are generally not applied to medical exposures. However, there is considerable opportunity for dose reductions in diagnostic radiology using the techniques of optimization of protection, and this is important since the second largest exposure to individuals is from medical exposures, and this is increasing particularly in the developed countries.

The risk from diagnostic radiography is a particularly important consideration for children—they are still developing and are more

sensitive to radiation-induced cancer than adults; in addition, they have a longer prospective life span, and hence, the period over which potential long-term side-effects may arise is greater (Brenner et al. 2001; WHO 2005). Therefore, care should be taken to minimize the number of unnecessary X-ray examinations, including dental X-ray examinations, and in optimizing the CT exposure settings when this procedure is indicated.

Health effects

Ionizing radiation causes two categories of adverse health effects: tissue reactions (also known as deterministic effects) and stochastic effects (ICRP 2007). Tissue reactions are caused by the ability of radiation to kill cells—if sufficient cells are killed then the tissue reaction occurs—and tissue reactions are characterized by a threshold dose below which the effect does not occur and above which the tissue reaction increases in severity. Stochastic effects are caused by non-lethal cell modification, which may develop into a cancer if the affected cell is somatic or into a hereditary abnormality if the affected cell is germ. Stochastic effects are understood to have no threshold dose, and at low doses or low dose-rates the risk is assumed to be directly proportional to the received dose, although this is not universally accepted. The overall risk of stochastic effects is dominated by the risk of cancer in the exposed individual (ICRP 2007).

Ionizing radiation causes damage to DNA either through direct physical interaction with DNA or through the nearby creation of free radicals that then chemically react with DNA. These interactions cause strand breaks in the DNA, and ionizing radiation is particularly efficient at producing clustered (i.e. localized) damage and consequently double-strand breaks. DNA repair mechanisms attempt to deal with the strand breaks caused by ionizing radiation, but double-strand breaks are especially difficult to repair accurately. Heavy damage to DNA from high acute doses of radiation often leads to a loss of DNA integrity that is sufficiently serious to lead to cell death, and when a particular proportion of cells in a tissue is killed then a tissue reaction occurs; the greater this proportion the more severe the tissue reaction. A cell may survive the DNA damage caused by radiation because the DNA is repaired correctly, but a cell may also survive with the DNA damage unrepaired or misrepaired, and this is understood to be the origin of the risk of cancer (in somatic cells) and hereditary effects (in germ cells).

The dose–response for stochastic effects is conventionally thought to be produced by a combination of the single traversal of the cell nucleus by a track of radiation and multiple traversals by independent tracks. The former occurs at low doses or low dose-rates of sparsely ionizing radiation and produces a linear term in the dose–response, while the latter occurs at moderate and high doses delivered at a high dose-rate and leads to an upward curving quadratic term; this is the mechanistic origin of the dose and dose-rate effectiveness factor (DDREF) of greater than 1 (conventionally, a value of 2). At high doses, cell killing becomes more likely, and the slope of the dose–response reduces as a consequence (since dead cells cannot contribute to the risk of stochastic effects). The linear no-threshold dose–response assumes that at low doses or low dose-rates the risk of non-lethal DNA damage of relevance to stochastic effects is directly proportional to the dose, and therefore, to the overall number of tracks crossing cell nuclei.

For high-LET radiations, the density of ionizations is such that the passage of a single particle through a cell nucleus does sufficient

damage to the DNA that only a linear term in the dose–response is apparent. Indeed, at the cellular level, the passage of a single alpha-particle track is a high-dose event, with a reasonable probability of inducing cell death, so the passage of two alpha particles is most likely to kill the cell. Thus, the dose–response for high-LET radiations is characterized by linearity, with a slope greater than that for the same absorbed dose produced by low-LET radiations, followed by a reduction in slope at high doses due to cell killing.

However, this picture is a greatly simplified version of reality, the biological mechanisms involved being very complex. For example, it assumes that DNA repair following acute low doses, producing just a few electron traversals of a cell nucleus, is not much more efficient (conventionally, twice as efficient—a DDREF of 2) than that following acute moderate doses, producing many electron traversals, and this assumption may not be correct. Further, there is evidence that epigenetic mechanisms may play a role in radiation-induced risk, in a way that is as yet unclear, and that these mechanisms may differ between high doses and low doses.

Some argue that since low doses produce a degree of DNA damage that is comparable to the level of damage that is constantly occurring through background biochemical processes, it is unlikely that low doses are harmful because the radiation-induced damage is ‘swept up’ by routine repair. Going even further, some argue that low doses of radiation stimulate the immune system, and so are beneficial (so-called ‘radiation hormesis’). On the other hand, some mechanisms of damage may be more effective at low doses than at moderate doses, leading to a supra-linear dose–response, and the bystander effect (whereby a cell hit by radiation adversely influences neighbouring cells that were not directly hit) is one example of such a mechanism because it affects more bystander cells at low doses than at moderate doses, where the effect is saturated because nearly all cells are hit. This serves to illustrate the complexity of radiobiology, and why risk estimates are still dominated by empirical epidemiological findings (ICRP 2007).

Cancer

It has been known for many decades that brief exposure to a dose of several gray leads to death through the killing of sufficient numbers of cells in vital tissues such as the red bone marrow, that is, death is caused by tissue reactions in radiosensitive tissues. An example from recent decades is the 28 emergency workers attending the Chernobyl accident in 1986 who died within a few months as a result of the high doses they received over a short period. Other tissue reactions include permanent and temporary sterility, depression of haematopoiesis, and eye lens opacities and cataracts.

Radiation has always been a natural part of our environment, and the types of radiation emitted from anthropogenic sources are fundamentally the same as those emitted from natural sources. At present it is not possible to distinguish between cancers resulting from radiation exposure (whether from man-made or naturally occurring sources) and those arising from other causes (National Research Council of the National Academies 2006; ICRP 2007; United Nations Scientific Committee on the Effects of Atomic Radiation 2008, 2010; IARC 2012). Consequently, in the absence of being able to determine the risk to human health from exposure to ionizing radiation from fundamental radiobiological principles, risk estimates must be derived empirically from epidemiological studies of suitably exposed groups of humans, augmented by an incomplete knowledge of radiobiological mechanisms. The evidence

that has been constructed from radio-epidemiological studies is substantial, and with the possible exception of tobacco, no other exposure has been studied so extensively. These epidemiological studies fall into four broad categories: studies of the Japanese survivors of the atomic bombings, those exposed for medical purposes either therapeutically or diagnostically, occupational exposure, and those exposed environmentally (National Research Council of the National Academies 2006; ICRP 2007; United Nations Scientific Committee on the Effects of Atomic Radiation 2008, 2010; IARC 2012).

The experience of the survivors of the atomic bombings of Hiroshima and Nagasaki in 1945 provides the principal (but certainly not the only) epidemiological evidence on which radiation risk estimates are based. A large cohort study, the Life Span Study (LSS), was established from information gathered during the Japanese national census in October 1950, and analyses of data generated by the LSS continue today (Preston et al. 2007; Ozasa et al. 2012; Hsu et al. 2013). The LSS consists of about 93,500 survivors, around 86,500 of whom have individually estimated tissue-specific doses—considerable effort has been expended on the reconstruction of tissue-specific doses received during the bombings (mainly from gamma-rays, but a component from neutrons), the latest database being the Dosimetry System 2002 (DS02). Of the LSS subjects, approximately 48,000 received non-trivial doses (>5 mSv), and of these approximately 18,000 received doses greater than 100 mSv, and approximately 2400 doses greater than 1 Sv; almost two-thirds of the non-trivially exposed survivors received doses less than 100 mSv (i.e. low doses). At the end of the last mortality follow-up (2003), 58 per cent of the LSS subjects had died, and 24 per cent of the deaths were due to cancer (Ozasa et al. 2012); 527 solid cancer deaths (8 per cent of such deaths among non-trivially exposed survivors) are estimated to be attributable to radiation exposure during the atomic bombings. As well as mortality, cancer incidence is ascertained in the LSS through two specialist registries, the most recent analysis of solid cancer incidence covering the period 1958–1998 (Preston et al. 2007), while the latest findings of the incidence of leukaemia, lymphoma, and multiple myeloma are from an analysis of covering the period 1950–2001 (Hsu et al. 2013). In a subset of the LSS, the Adult Health Study (AHS), survivors participate in regular medical examinations to record clinical parameters such as blood pressure. Other relevant cohorts are those who were exposed *in utero* and the offspring of survivors who were conceived after the bombings, the latter group providing information on the risks of the heritable effects of exposure.

Early support for the initial findings of the studies of the Japanese atomic-bomb survivors came from investigations of long-term health effects among patients treated with radiotherapy, in particular British patients irradiated for ankylosing spondylitis and US women treated with radiation for cancer of the uterine cervix (United Nations Scientific Committee on the Effects of Atomic Radiation 2008). Now there is evidence deriving from a wide range of radiotherapeutic treatments such as various groups of cancer survivors, children irradiated for ringworm of the scalp or haemangioma of the skin or for an enlarged thymus, and patients injected with radium-224. Patients exposed to radiation for diagnostic purposes are providing increasingly useful information as the use of CT scans increases, but those X-rayed to monitor treatment for tuberculosis or for scoliosis, and fetuses exposed during an abdominal X-ray examination of the pregnant mother, have already provided

valuable evidence on the risks of low-level exposures. A recent large cohort study of British children who received at least one CT scan found evidence of an increased risk of brain tumours and leukaemia that was related to the dose of radiation estimated to have been received from the scans (Pearce et al. 2012). An interesting group of patients is those injected with the radiographic contrast medium Thorotrast, which unfortunately was thorium-based and therefore radioactive and gave large doses to certain tissues, such as the liver and red bone marrow.

Radiologists and radiographers have been subjects of study since the early uses of radiation in medicine, and US radiologists provided the first indication that radiation could cause leukaemia (March 1944). Of particular interest are groups of underground hard-rock miners (e.g. uranium and tin miners) who inhale the radioactive gas radon and its decay products, which irradiate the lungs (mainly with alpha-particles); and in the past, exposures have been high. Workers (mainly young women) who applied radium-based luminous paint to watch and instrument dials inadvertently ingested radium (an alpha-emitter) through the habit of licking the tips of paintbrushes ('tipping'), and some workers ingested large quantities of radium, which deposits in bones. Of increasing importance is the evidence obtained from the study of groups of nuclear industry workers, especially those who worked during the early years of the industry when doses were comparatively high relative to those received today. Large worker studies are providing valuable information on the effects of protracted low-level exposure, and international collaborations have the potential to produce statistically powerful results. Special cases are those workers involved in dealing with emergencies, such as the 'liquidators' who were brought in to deal with the aftermath of the Chernobyl accident in 1986, and those from the early years of operations at the Mayak nuclear complex in Russia who were particularly highly exposed to both external sources of radiation and plutonium, an alpha-emitter that was inhaled in relatively large amounts during early weapons production.

Radon in homes has been a subject of substantial scientific attention because globally this is the source of the largest exposure to radiation for the great majority of people. Large case-control studies that take into account the important contribution of risk posed by cigarette smoking, have examined the risk of lung cancer arising from residential exposure to radon, and appropriately combined findings from these studies have produced radon-related risk estimates that are compatible with those obtained from underground hard-rock miners (IRCP 2010). Exposure to other sources of natural background radiation, in particular terrestrial gamma radiation, has also been studied, notably in those parts of the world where such exposures are materially greater than the global average. A well-designed study of cancer incidence in Kerala (India) has not found an excess cancer risk related to radiation exposure (Nair et al. 2009), although findings are, as yet, compatible with those of the LSS. A large British case-control study concentrating on childhood leukaemia has found evidence of an excess risk from background gamma radiation that is consistent with risk models derived from the Japanese atomic-bomb survivors (Kendall et al. 2013).

Radioactive contamination from accidental and routine discharges from nuclear installations has been another area of study, radioactive iodine releases from the accident at Chernobyl and substantial pollution of the Techa River by liquid effluent from the Mayak complex being notable examples. The releases during

the Fukushima accident in 2011 provide another opportunity for study, although it would appear that doses are not sufficiently large for any effects to be detectable (WHO 2012a, 2012b). Fallout from atmospheric nuclear weapons testing, especially at its peak in the late 1950s and early 1960s, has provided another source of exposure for study, and those resident in the vicinity of weapons testing sites (such as the Semipalatinsk Testing Site in present-day Kazakhstan) are of particular interest. Finally, a group of Taiwanese residents was irradiated by gamma radiation from ^{60}Co -contaminated steel accidentally used in building construction, and this group is being followed.

Epidemiological studies have clearly established that acute exposure to moderate and high doses of ionizing radiation (> 100 mGy of sparsely ionizing radiation) increases the risk of cancer (National Research Council of the National Academies 2006; ICRP 2007; United Nations Scientific Committee on the Effects of Atomic Radiation 2008, 2010; IARC 2012). However, all types of cancer do not have equal sensitivity to radiation induction—acute leukaemia, thyroid, and female breast cancer have a high sensitivity, whereas chronic lymphocytic leukaemia, Hodgkin's lymphoma, and malignant melanoma of the skin have a low sensitivity, with other cancers falling somewhere in between from higher (e.g. lung and colon cancers) to lower (e.g. pancreatic and prostate cancers) sensitivity. Leukaemia was the first cancer to be definitively linked to radiation exposure when a clear excess risk of the malignant disease was detected in the Japanese atomic-bomb survivors in the early 1950s (although unusually high numbers of cases were reported by alert clinicians in the late 1940s), and there had been earlier reports of elevated levels of leukaemia among radiologists (March 1944), which had been difficult to interpret at the time. As the follow-up of the atomic-bomb survivors progressed, raised mortality and incidence of other cancer sites were found to be related to exposure, and this evidence was supplemented by other exposed groups, such as an increased risk of a number of solid cancers among patients treated with radiotherapy for a variety of diseases, a marked excess of bone cancer among those groups with high intakes of radium, an excess risk of lung cancer among underground hard-rock miners exposed to radon, and an excess risk of liver cancer among the Thorotrast patients with high body burdens of thorium. Recently, the Chernobyl accident has produced a notable excess risk of thyroid cancer among those who as children inhaled and ingested high levels of radioactive iodine released during the accident, an excess that is compatible with that found among those exposed as children to external sources of radiation.

The most recent analysis of leukaemia mortality among the LSS cohort found that a linear-quadratic dose-response best described the data, and that the excess relative risk was 3.1 (95 per cent CI: 1.8–4.3) at 1 Gy red bone marrow dose and 0.15 (95 per cent CI: –0.01–0.31) at 0.1 Gy, based on 318 deaths (Ozasa et al. 2012). About half of the leukaemia deaths among the non-trivially exposed (> 5 mGy) survivors are attributed to irradiation during the bombings. However, modelling demonstrates a marked variation of risk with age-at-exposure and time-since-exposure: for young children, the excess relative risk (ERR, the proportional increase in risk) rises to a peak of approximately 50 some 7 years after exposure and then falls away to approximately 5 some 30 years after exposure—a temporal wave of excess risk—while for exposed adults this wave is hardly apparent, with the ERR remaining below 5 at all times after exposure. From the latest datasets for the mortality and incidence

of all solid cancers (malignant diseases other than leukaemia, lymphoma, and multiple myeloma) among the survivors, a linear dose–response fits the data best, with a slope of the ERR for solid cancer mortality for a survivor exposed at age 30 years and at an attained age of 70 years of 0.47 (95 per cent CI: 0.38–0.56) Gy⁻¹, based upon almost 11,000 deaths. The ERR coefficients for leukaemia and solid cancer incidence are similar to those for mortality (Preston et al. 2007; Ozasa et al. 2012; Hsu et al. 2013). However, as already mentioned, there is notable variation in the ERR/Gy for individual sites of cancer, the ERR for the incidence of breast, thyroid, and non-melanoma skin cancers being high while that for cancers of the rectum and uterus are low.

Risk models have been developed from the cancer data for the Japanese atomic-bomb survivors, supplemented by other data sources where these are found to make a useful contribution to evidence, such as for leukaemia and for thyroid and breast cancers following exposure for medical therapy. Lung cancer among radon-exposed underground hard-rock miners has provided a valuable source of information on the risk of radon-induced lung cancer, which is compatible with the risk of lung cancer among those exposed residentially to, in general, much lower levels of radon. The influence of tobacco smoke upon the risk of lung cancer is especially important to take into account in such studies, and it would appear that radiation and cigarette smoke interact to produce a combined risk of lung cancer that is more than additive, so that smokers are at a greater risk of radon-induced lung cancer than non-smokers.

In general, the findings of the studies of the Japanese atomic-bomb survivors are compatible with those from other exposed groups, although comparisons are often not straightforward. For example, doses from radiotherapy are usually localized and high, with the objective of killing the target cells, but the unintentional irradiation of healthy cells can also lead to their being killed and thereby to a reduction in the risk per unit dose of cancer. Doses away from the target are received from scattered radiation and are difficult to compute accurately, although modern dose reconstruction methods are improving dose estimates. Of growing importance are studies of acute low doses or protracted low dose-rates, because these exposure circumstances directly test the assumptions required for everyday radiological protection. Preliminary findings of such studies, for example, of patients receiving CT scans, those living in areas affected by radioactive contamination, or nuclear industry workers, indicate that there is an increased risk from low doses/dose-rates (at least, for some types of cancer, notably leukaemia), but that this risk is not greatly different from the predictions of conventional risk models.

Other outcomes

Epidemiological studies have failed to produce definitive evidence that exposure to ionizing radiation increases the risk of heritable genetic effects in the descendants of those exposed (ICRP 2007). Even the follow-up of more than 30,000 offspring of the Japanese atomic-bomb survivors who were conceived after the bombings has not provided clear evidence of an inherited effect from parental exposure. Nonetheless, large experiments involving laboratory animals, mainly mice, have produced unambiguous evidence that irradiation of parents does raise the risk of hereditary effects in offspring. The risk of radiation-induced hereditary effects in humans derived from this evidence suggests that this risk is much lower than the risk of cancer in the exposed individual.

The lens of the eye is sensitive to radiation-induced cataracts, and recent evidence indicates that the threshold for the production of cataracts, at around 500 mGy of low-LET radiation, is much lower than the 5 Gy previously considered as a threshold dose (ICRP 2012). This evidence comes from the Japanese atomic-bomb survivors, the Chernobyl ‘liquidators’, and medical staff.

The embryo and fetus are sensitive to radiation-induced developmental effects, such as, early in pregnancy, congenital malformations (although death may occur before birth defects become likely) (ICRP 2007). Severe mental retardation was found among Japanese atomic-bomb survivors exposed *in utero* to high doses during 8–15 weeks of gestation, and less so at 16–25 weeks.

An issue requiring resolution is whether low doses/dose-rates are capable of raising the risk of non-cancer somatic diseases, in particular diseases of the blood circulatory system, such as heart attack and stroke (ICRP 2012). It has been known for some time that high doses can lead to an excess risk of these diseases, and this was attributed to tissue damage produced during such exposure, but epidemiological evidence is mounting for an effect at lower doses. However, a mechanism has yet to be identified, and the confounding effects of major (non-radiation) risk factors cannot yet be reliably eliminated as responsible for the association. Nonetheless, the potential risk of circulatory disease following low-level exposure to radiation is considered sufficiently important that significant research effort is being devoted to its investigation.

Policy and prevention

The ICRP, in its latest assessment of evidence, provides detriment-adjusted nominal risk coefficients for all cancers combined: 5.49 per cent Sv⁻¹ for the whole population and 4.07 per cent Sv⁻¹ for the working population (ICRP 2007). The detriment-adjusted nominal risk coefficients for hereditary effects are: 0.2 per cent Sv⁻¹ for the general population and 0.12 per cent Sv⁻¹ for a working population. Consequently, the aggregated detriment-adjusted nominal risk coefficients for stochastic effects following low-level exposure to radiation are 5.7 per cent Sv⁻¹ for a general population and 4.2 per cent Sv⁻¹ for a working population. These risk coefficients form the technical basis of the current framework of radiological protection recommended by the ICRP, and give rise to dose limits: for workers, the limit is an effective dose of 20 mSv per year averaged over a defined period of 5 years (with a maximum of 50 mSv in any one year), and for the general public the limit is an effective dose of 1 mSv in a year (although in special circumstances a higher dose could be received in any one year provided the annual average is 1 mSv over a 5-year period). These limits do not apply to medical or naturally occurring sources of exposure, although residential exposure to radon and its radioactive decay products in some areas of the world are assessed to produce a sufficiently high risk of lung cancer that remediation measures are required to reduce the exposure.

The three key principles of radiological protection remain: (1) the justification of activities that could cause or affect radiation exposures, (2) the optimization of protection in order to keep doses as low as reasonably achievable, and (3) the application of dose limits (ICRP 2007). The recommendations state:

1. No practice involving exposures to radiation should be adopted unless it produces sufficient benefit—to the exposed individuals or to society—to offset the detriment it causes.

Table 7.2.4 Recommended dose limits

Type of limit	Occupational	Public
Effective dose	20 mSv per year, averaged over defined periods of 5 years, with a maximum of 50 mSv in any one year ^a	1 mSv in a year
Annual equivalent dose in: Lens of the eye	20 mSv per year, averaged over defined periods of 5 years, with a maximum of 50 mSv in any one year	15 mSv
Skin	500 mSv	50 mSv
Hands and feet	500 mSv	—

^a The basis for the control of the occupational exposure of women who are not pregnant is the same as that for men. However, once pregnancy has been declared, the embryo/fetus is protected—the effective dose limit for the embryo/fetus is 1 mSv.

Source: data from International Commission on Radiological Protection (ICRP), *The 2007 Recommendations of the International Commission on Radiological Protection*, ICRP Publication 103, Copyright © 2007.

2. In relation to any particular source within a practice, the magnitude of individual doses, the number of people exposed, and the likelihood of incurring exposures (where these are not certain to be received) should all be kept as low as reasonably achievable, economic and societal factors being taken into account.
3. The exposure of individuals resulting from the combination of all the relevant practices should be subject to dose limits, or to some control of risk in the case of potential exposures; hence, ensuring that no individual is exposed to radiation risks that are judged to be unacceptable from these practices in any normal circumstances. Dose (or risk) constraints are used to restrict to upper bounds the dose received (or potentially received) from a specific source.

Restrictions on effective dose sufficient to ensure the avoidance of deterministic effects in all body organs and tissues, and that limit the risk of stochastic effects to acceptable levels, are shown in Table 7.2.4.

Conclusions

The nature, frequency, and severity of adverse effects on human health caused by exposure to ionizing and non-ionizing radiation vary depending on the intensity and other exposure parameters, and are highly frequency dependent. Potential effects range from rapidly fatal injuries to birth and hereditary defects, cancer, and other chronic diseases. Many effects occur only at high levels and are controlled or reduced by applicable exposure standards. In this chapter, our main emphasis is on exposures common in everyday life and on long-term effects, which are typically of most concern to the public.

The IARC classified ionizing radiation and UV radiation as a ‘known’ or Group 1 carcinogen, while ELF magnetic fields and RF fields have been classified as a ‘possible human carcinogen’, or a Group 2B, and static fields as well as ELF electric fields have been assigned Group 3 (not classifiable as to carcinogenicity to humans). Intermediate frequencies and infrared radiation have not yet been classified as to their carcinogenic potential.

As it is not possible to eliminate exposure to ionizing radiation, these exposures are kept to a practical minimum. Most recommend

avoiding solar UV exposure in order to facilitate the prevention of skin cancers. Because recent literature suggests beneficial effects of solar UV exposure it is critical to develop and adopt a well-balanced set of recommendations regarding this exposure. For ELF magnetic fields, given exposure prevalence, considerable scientific uncertainty, and limited public health impact, no- and very low-cost precautionary measures are justified. For RF, potential risk could affect a large number of people because of the ubiquitous nature of the exposure. Thus, given the important gaps in knowledge and availability of no- to low-cost measures, such as use of hands-free devices to reduce exposures from mobile phones, such measures can and should be adopted.

Rigorous studies capable of addressing knowledge gaps are urgently needed, particularly for rapidly growing technologies such as mobile phones, MRI exposures, IF anti-theft and device tagging, and modern magnetic levitation (maglev) systems.

Environmental exposure assessment: modelling air pollution concentrations

John Gulliver and Kees de Hoogh

Introduction to environmental exposure assessment

Epidemiological studies ideally would have access to information on continuous lifetime air pollution exposures at the individual level that are suitably resolved in space and time for studying specific diseases. Air pollution exposures are a function of the indoor and outdoor locations (i.e. micro-environments) that people visit during their daily routines, are variable over hours, days, and weeks due to routine work and leisure patterns, and change over months and years due to activities associated with different stages of childhood and adulthood. Over different periods of life the sources of air pollution can be many and variable; they occur at home (cooking, heating), outdoors and during journeys (traffic, industry, shipping, aircraft), and work (i.e. various ‘occupational’ exposures). Capturing representative information on exposures, particularly for active population subgroups, for even relatively short periods of life, is thus challenging.

Air pollution monitoring has been ongoing in developed countries for decades. The United Kingdom, for example, has a network of air pollution monitors for black smoke (BS) and sulphur dioxide (SO₂) in operation since 1955. In the last 20 years technology has been developed to allow automatic monitoring of a range of air pollutants (e.g. nitrogen dioxide, particulates, ozone) at high temporal resolution (i.e. < 1 hour) using different measurement techniques depending on the type of pollutant. Many medium-to-large cities typically have continuous measurement of air pollutants at one or more dedicated (i.e. fixed-site) locations. Some mega-cities have detailed networks of air pollution monitors; London, for example, has over 100 measurement site locations as part of the national ‘Automatic Urban and Rural Network’ (AURN) and is supplemented by local government sites. These sites provide the basis both for monitoring changes in air quality to provide information to the public on the air that they breathe and as a policy tool for assessing emissions interventions and controls (e.g. low emissions zones, congestion charging). To what extent these sites provide information representative of air pollution exposures in an epidemiological context is questionable. Using the nearest air pollution monitor, for example, has been shown to be a poor marker for exposure (Gulliver et al. 2011), especially in urban areas that are

characterized by complex air pollution surfaces due to dense transport networks, buildings, industrial sources, and terrain.

Portable air pollution sensors if sufficiently small and lightweight offer an opportunity to measure more ‘personalized’ exposures (e.g. the VE³SPA study; Montagne et al. 2013). These sensors are becoming more portable and cost-effective and can be used on a relatively small number of individuals (e.g. cohort or panel studies). For large numbers of individuals air pollution monitoring is not practical.

For large cohorts or population-wide studies the alternatives are models or proxies of exposures. Most exposure assessments have, however, been simple and crude, providing proximity measures (e.g. distance from road) or relying on extrapolation from measurements of air pollution concentrations. Methods such as spatial interpolation (e.g. inverse-distance weighting, splines, trend surface analysis) and geo-statistical techniques (e.g. Kriging) can provide large geographical scale surfaces from monitored concentrations (Jerrett et al. 2005), but have been shown to perform poorly where monitoring networks are sparse or over complex urban surfaces (Gulliver et al. 2011). Combining background air pollution measurements with information on proximity to locally varying sources (e.g. roads) can improve spatial resolution of exposure estimates (Hoek et al. 2001), but this does not allow for consideration of the variations in source emissions over time.

Two techniques have been developed which are now widely used to undertake air pollution exposure assessment: dispersion modelling and land use regression (LUR) modelling (also known as regression mapping). Whilst dispersion modelling would likely be the preferred method as it simulates the physical characteristics of the dispersion environment (Carruthers et al. 2000), it is often impractical for exposure assessment for the following reasons: (1) most areas do not have detailed emissions inventories for different air pollutants, (2) it is computationally intensive for large geographical areas, and (3) most dispersion models are run without considering the spatially varying influence of land cover (types of land use, buildings etc.).

Epidemiological studies thus increasingly turn to LUR modelling as an alternative to dispersion modelling. LUR modelling, developed by Briggs et al. (1997, 2000) in the United Kingdom, uses proximity measures such as distance and circular buffers of varying sizes to summarize around point locations (i.e. monitoring sites,

addresses) geographical features (e.g. land use, road networks, traffic, terrain, etc.) which explain variability in monitored concentrations. The intersection of buffers with geographical features and measures of distance to sources are undertaken in a geographical information system (GIS). A typical model might have 50–100 variables being considered for inclusion. The variables are assessed one by one, or grouped by variables type (e.g. roads), in regression analysis in terms of their correlation with monitored concentrations of air pollution and then in combination to find the best set of variables (i.e. variables that collectively explain the highest proportion of variation in monitored concentrations). Models are typically developed against a set of ‘training’ monitoring sites and evaluated on a set of ‘test’ (i.e. held-out) monitoring sites from the same monitoring network.

Many different LUR models have been developed over the last 15 years. Two substantive reviews of the structure and application of LUR models have been done in recent years (Ryan and LeMasters 2007; Hoek et al. 2008). In many locations it is not possible, however, to develop LUR models due to a lack of information on monitored concentrations of pollutants and/or information on source emissions. One option is to consider using a model developed elsewhere or from a different time period. These reviews raise questions about the transferability of LUR models in space (between different cities, from small areas to larger areas etc.) and time (i.e. back extrapolation), but so far these issues have not received much attention. Important considerations in the transfer of LUR models are threefold: (1) are the types and resolution of source data comparable between the area where the model was developed and the area where it will be applied, (2) have the sources of air pollution changed over space and/or time, (3) is there air pollution monitoring data in the area where the LUR model will be applied to either evaluate the transfer of an existing model or calibrate the model for the target area/time period?

This chapter describes how to undertake the various steps in LUR modelling from initial data collection through to model evaluation (see ‘Developing land use regression models’ section); the goal is to provide practical guidelines (i.e. dos and don’ts) for undertaking LUR modelling. The ‘Transferability of LUR models in space and time’ section addresses the issue of transferring land use regression models in space and time between different areas (i.e. city-wide or regional models) of the United Kingdom, and extrapolating models to different time periods both within areas where models have been developed and to other areas without locally developed models.

Developing land use regression models

Requirements for LUR modelling

It is firstly important to understand the data and software requirements for LUR:

1. Monitoring site coordinates (X, Y) with monitored concentrations of air pollutants for the period of study (i.e. months, years) (these data are used to develop and evaluate the performance (i.e. validation) of the resulting LUR model).
2. GIS data that represent the emissions sources (e.g. road geography, traffic flows, area of industrial land, housing, and population) and characteristics of the dispersion environment (altitude, terrain, meteorology, buildings).

3. GIS software for developing and extracting information on potential explanatory variables and multivariate statistical software for regression analysis.

Monitored concentrations of air pollutants

Many cities have either their own municipal monitoring networks (e.g. <http://www.londonair.org>) or contain monitoring sites which are part of a national network (e.g. <http://www.airquality.co.uk>) usually administered by government agencies. For some pollutants (e.g. fine particulates) there often will only be a handful of monitoring sites within even larger cities and many small-to-medium urban areas will not have air pollution monitoring. It is therefore often necessary to undertake bespoke air pollution monitoring campaigns, particularly in relation to epidemiological studies (Cyrus et al. 2012; Eeftens et al. 2012b), to obtain a sufficiently dense network of monitoring sites to get a representative sample of air pollution variability across the population being studied. There is no rule on the minimum numbers of sites that are needed to develop an LUR model, but typically a minimum of 30–40 sites will be used; it may be possible to develop models with as few as 20 sites where the study area is relatively small or the emissions sources and geographical characteristics of the dispersion environment are fairly homogeneous. Indeed, in the Netherlands, LUR models were shown to be valid when 20–30 air pollution measurement sites were used to develop models (Wang et al. 2012).

Ideally, monitoring sites will represent a range of site types (e.g. roadside, industrial land, urban background, remote/rural, coastal/inland) with a focus on residential areas if the purpose of the LUR model is for population exposure assessment. Roadside sites should furthermore be representative of the range of traffic flows in the area and characteristics such as street canyons, arterial roads in open suburbia, etc.

Predictor variables

GIS data needs to be of sufficient spatial resolution to accurately depict emission sources and the dispersion environment with respect to the geographical units being used for exposure assessment (e.g. address, postcode, census tract). Ryan and LeMasters (2007) provide a review of the different types of variables used in different studies over the first 10 years after LUR was introduced.

Road traffic is the major source of air pollution in many urban areas and is often ubiquitous because of dense road networks. Ready-made data on road geography is commonplace and some areas will also have access to information on traffic volumes on main roads. Data on land cover is also usually available or can be derived using remote sensing techniques or digitized from aerial photographs. Although there may be highly resolved land cover data at the local level, where harmonized LUR approaches (i.e. consistent exposure assessment) are needed at national or international level (e.g. multicity cohort studies) more coarse land cover data might be used; for example, in the ESCAPE project (Eeftens et al. 2012a; Beelen et al. 2013; de Hoogh et al. 2013) the CORINE pan-European land cover data set was used to provide a harmonized data input for all areas even though better data was available in some study areas.

Many LUR models include data on population as a surrogate for emissions related to domestic heating, domestic wood burning, or perhaps emissions from minor road sources not included in traffic

data sets. Some LUR models include information on both population and land cover categories for housing from the same zones, but this raises questions about 'double-counting' of emissions sources as population and housing density overlap.

Traffic and land cover classes for the built environment (housing, industry, etc.) are expected to have a positive direction of effect (i.e. increase) on air pollution concentrations. Sometimes 'natural' rural land cover classes are included in LUR models to have a negative effect on pollutant concentrations (i.e. decrease). Open areas of water or woodland, for example, may be useful in LUR to represent locations with no source emissions. Some rural land cover classes might on the other hand represent areas associated with pollution emissions (e.g. farming, bio-composting etc.).

Many countries have digital models of terrain (DTM) and elevation (DEM) through national mapping agencies, typically of spatial resolution between 10 and 100 m from which altitude can be derived for point (e.g. monitoring site) locations. Where not available locally there are international models at coarser resolution (e.g. SRTM 90 m Digital Elevation Data (<http://srtm.csi.cgiar.org/>)).

GIS software

Preparing data and extracting variables from GIS for LUR modelling is relatively straightforward due to the major improvements in computing power and menu-driven GIS software. There are a wide range of commercially available GIS software with a growing number of freely available open-source GIS. Moreover, open-source statistical software (e.g. R) means that LUR modelling is open to everyone who can obtain both data representative of emissions sources and the dispersion environment and modest computing power.

Developing land use regression models

The typical set of steps involved in developing and applying an LUR model are: (1) extract predictor variables for different monitoring site locations, (2) use regression analysis to determine the 'best' set of predictor variables and associated coefficients (i.e. 'weights'), and (3) apply the model at locations for exposure assessment. Fig. 7.3.1 summarizes the steps taken to develop an LUR model with variables on traffic and housing.

Variables for LUR are normally extracted from digital data in a GIS. Each variable type (e.g. roads, land cover) is usually summarized using circular 'buffers' of increasing radii (i.e. using GIS tool/functions) to represent the distances up to which (i.e. sphere of influence) source emissions should affect concentrations at each location (i.e. air pollution monitoring sites). Variables for road length, for example, might be summarized in circular buffers (i.e. sum of road length) at 50 m intervals up to 1000 m, but it is unlikely in most situations that roads beyond this distance would directly influence air pollution concentrations. In addition to circles, measures of distance (e.g. distance to road, distance to coast etc.) can be calculated in GIS for LUR using standard functions (i.e. 'NEAR').

Regression analysis

The next stage is to undertake the regression analysis to select variables for inclusion in the model. Variables extracted for each monitoring site location in a GIS are usually exported to statistical software for the regression analysis. The goal of regression analysis is to select the variable(s) that explain the highest proportion of variability in pollutant concentrations at monitoring site locations. The

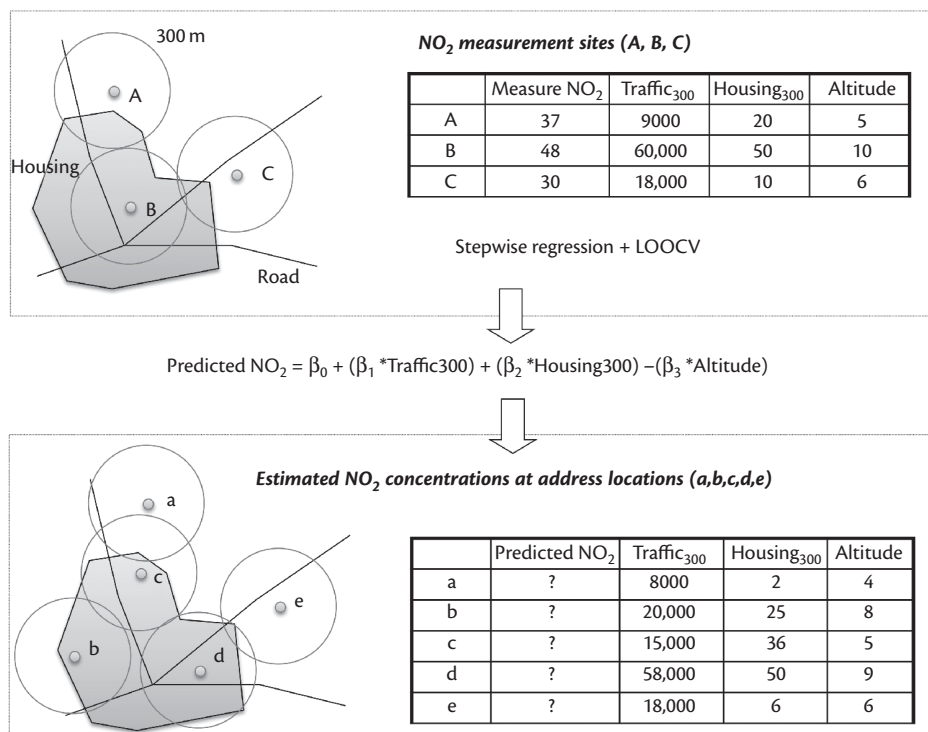

Fig. 7.3.1 Steps undertaken in a GIS to extract and summarize predictor variables.

focus of this procedure is thus to maximize the correlation between the predictions and observations whilst minimizing model errors.

There is no singly recognized process for regression analysis, but a general set of 'rules' has evolved for the development of LUR models as shown in Box 7.3.1 (see also Hoek et al. 2008).

Su et al. (2009) suggested a formalized procedure for the development of LUR called ADDRESS: 'A Distance Decay REgression Selection Strategy'. This method is essentially the same as the one described in Box 7.3.1 but ADDRESS used a graphic representation of the changes in the correlation (R^2) between each variable and measured concentrations with different buffer distances.

The most common statistical measure used to assess the process of model building is the coefficient of determination, and commonly referred to as R^2 (pronounced as 'R-squared'). In essence, this is a measure of error between observations (e.g. pollutant concentrations) and predictions expressed as a proportion of the overall variability in observations:

$$R^2 = \frac{SSE}{SSy} = 1 - \frac{\sum_{i=1}^n (O_c - P_c)^2}{\sum_{i=1}^n (O_c - \bar{O}_c)^2} \quad (7.3.1)$$

Where:

SSE is the sum of the square of errors between observations and model predictions.

SSy is the sum of the squares of the observations (e.g. measured concentrations)—in other words, the sum of the squared differences between each observation and the mean of all observations (i.e. similar to variance).

O_c is each observation (e.g. measured concentration).

P_c is each model prediction (i.e. prediction at each monitoring site from a given set of LUR variables).

\bar{O}_c is the mean of observations.

Values of R^2 range from 0 to 1. Thus, R^2 will tend towards a value of 1 if errors are small relative to the variance in measured concentrations of pollutants; conversely, if errors are large relative to the variance in measured concentrations then R^2 will tend towards zero. Values of r^2 (i.e. ' r ' for a single variable) are the same as the square of Pearson's correlation coefficient (r) when an intercept is included in the model and the outcome (i.e. measured concentration) is predicted from only one explanatory variable. If an intercept is included and there are multiple variables then the coefficient of determination (R^2) is used.

A variant of R^2 is the *adjusted* R^2 (i.e. $adj.R^2$). A model with ten variables is likely to be less robust (i.e. it is unlikely that, e.g. variables 6 to 10 are very strong predictors) than a model with three to four strong variables. Thus the $adj.R^2$ penalizes the R^2 for the number of parameters in the model:

$$adj.R^2 = 1 - \left[\frac{(1 - R^2)(n - 1)}{n - k - 1} \right] \quad (7.3.2)$$

where:

n is the number of observations (outcomes) in the regression.

k is the number of parameters in the regression not counting the constant.

Box 7.3.1 Guidelines for creating regression models

1. Before the LUR model development perform descriptive analyses:
 - a. Plot distributions of concentrations and predictor variables (e.g. boxplots to assess variation and outliers).
 - b. Check for normality of measured concentrations (consider log-transformation of data for skewed distributions).
 - c. Correlation between predictor variables to check for collinearity.
2. Try to enter explanatory variables in a supervised stepwise manner, so that you include your most important predictors first.
3. The sign for each coefficient in the model must conform to the expected direction of effect (i.e. positive values for emissions sources and negative values for variables which represent areas without emissions sources, e.g. semi-natural land).
4. Variable with highest increase in adjusted R^2 should be included if:
 - a. increase in adjusted $R^2 > 1$ per cent (a typical threshold)
 - b. β coefficient has pre-specified direction
 - c. direction for other variables does not change.
5. Each variable in the model should be significant (e.g. $p < 0.05$).
6. Following point 2, variables entered later in the process should not be maintained if they cause variables already in the model to invalidate guidelines 3, 4, or 5.
7. Avoid double counting by excluding overlapping buffers. For example, including roads in 0–20 m and 20–40 m is valid, but including roads in 0–20 m and 0–40 m is not.
8. Gaps in the buffers should also be avoided. For example, roads in 20–40 m should not be included unless roads in 0–20 m is already in your model.
9. Final model checked for:
 - a. influential observations: Cook's D
 - b. heteroscedasticity of the residuals
 - c. normality of the residuals
 - d. spatial autocorrelation of the residuals (kriging or Moran's I).

As Equation 7.3.2 implies, the larger the number of parameters (k) in the model then the lower the $adj.R^2$. *Adjusted* R^2 is not normally used in model evaluation (see later) as the comparison then is univariate (i.e. the predicted concentrations compared to the measured concentrations).

In seeking as high as possible correlation between the predictor variables and the observations, the goal is also to reduce the model prediction errors; errors are commonly assessed in model development by the standard error of the estimate (SEE). SEE is defined in Equation 7.3.3:

$$SEE = \frac{\sqrt{\sum (Y - Y')^2}}{N} \quad (7.3.3)$$

where:

Y is the observed value (measurement concentration at a monitoring site).

Y' is the prediction for a given set of variables.

N is the number of pairs of observations and predictions.

One concern in multiple-regression is collinearity between model variables (i.e. 'double-counting'). The variance inflation factor (VIF) is a useful indicator of collinearity between variables at each stage of model development. As a general rule, values of VIFs less than 5 are acceptable but LUR models often use a more stringent threshold (e.g. maximum VIF of 3); that is, as applied in the ESCAPE study (e.g. Eeftens et al. 2012a; Beelen et al. 2013). In LUR, collinearity might occur when overlapping buffers are used (e.g. road length in buffers 0–100 m and 0–200 m) or variable types are included more than once (e.g. urban land within 1000 m and housing within 1000 m), hence the guidelines for handling variables in LUR shown in Box 7.3.1.

Cook's distance is a method of identifying outliers in model development. For example, one or two sites might suppress the predictive capacity of a particular variable because their site characteristics are unusual; Cook's distance is particularly useful to filter out problematic sites when the number of sites used for model development is relatively small.

Model errors should be checked for heteroscedasticity (i.e. model errors should be proportionally the same over the range of pollutant concentrations) and normally distributed—prerequisites of regression modelling. Finally it is useful to map model residuals (standardized by concentration) to see whether models perform poorly in a particular part of the study area (i.e. clustering of residuals). Moran's I (Getis and Ord 1992) is commonly used, and available in some GIS software, as a quick, 'one-shot' assessment of whether model residuals are spatially dependent; in other words, Moran's I (denoted by ' Z ') is used to detect whether there are clusters of relatively large residuals from the LUR model. A value of -1 represents complete dispersion, a value of zero represents a completely random distribution of residuals, and a value of 1 represents complete clustering of residuals. A value of Moran's I tending towards 1 and statistically significant ($p < 0.05$), indicates that the model is not working well in a particular part of the study area, which may relate to one or more weak variables in the model.

Evaluating model performance

In convincing the rest of the world that your model is valid for use in exposure assessment, it is commonplace to compare predicted concentrations from models with measured concentrations from fixed-site air pollution monitors. The most useful assessment of model performance is to make predictions for locations that were not used to develop the parameters in the model (i.e. an independent test).

One possibility is to select some of the 'pool' of sites for model development and reserve some sites for model evaluation. The evaluation sites are often referred to as 'out-of-sample' or 'held-out' based on methods development in statistics. In the development of national scale models for historic exposure assessment of BS and SO₂ Gulliver et al. (2011), for example, made a stratified random sample of 75 per cent of sites to be used for model development and used the remaining 25 per cent of sites for model evaluation. The stratification was to ensure a representative numbers of each monitoring location by site type (i.e. residential, industrial, rural, etc.) and by geographic location (i.e. region) both in the training and evaluation sets. Out-of-sample evaluations are often constrained, however, by the number of available monitoring sites so other approaches are

needed for model evaluation. In situations where the number of sites available for LUR modelling is relatively low (e.g. 20–40) then cross-validation is often applied. Leave-one-out-cross-validation (LOOCV) has been used in several LUR studies with limited monitoring sites (Basagaña et al. 2012; Wang et al. 2012). LOOCV operates, as the name suggests, by re-running the regression analysis with one monitoring site removed from the training data each time ($n - 1$ sites) to derive new coefficients for model variables and then predict the pollutant concentration for the removed site. This is repeated for all sites in turn and then model performance is assessed on the LOOCV predictions.

A range of performance statistics have been used to evaluate LUR models. Commonly used measures are summarized in Table 7.3.1 including a description of their purpose.

Case study on model development and evaluation

This next section applies the procedures just described to develop and evaluate an LUR model for a real-world example. As part of the multicentre ESCAPE (European Study of Cohorts and Air Pollution Effects) project, a bespoke measurement campaign for particulate matter (PM₁₀, PM_{2.5}, PM_{coarse}, PM_{2.5} absorbance) and oxides of nitrogen (NO_x, NO₂) was undertaken in the Thames Valley region (i.e. London and the surrounding area towards Oxford) during 2010 as the basis for developing LUR models (Cyrys et al. 2012; Eeftens et al. 2012b). Routine monitoring sites were not used in the ESCAPE study because they are not comparable across Europe (i.e. different measurement techniques) and the location of routine monitoring sites do not capture the full extent of intra-urban variation of air pollution. The Thames Valley study area lies in the South East of England and has a total population of approximately 15.5 million with around 8 million people living in the area known as Greater London (Fig. 7.3.2). The area is characterized by road traffic—especially in the cities of London, Oxford, and Reading—housing, commercial buildings, light industry, and mainly covers gently undulating, lowland terrain.

Monitoring sites were chosen to reflect areas with different geographical characteristics and the distribution of population, hence the highest concentration of sites in the Thames Valley study is in London (see Fig. 7.3.2).

The measurement data collected for NO₂ in the Thames Valley area are used here to demonstrate the main processes involved in developing an LUR model. During ESCAPE, air pollution monitoring was also undertaken in Bradford. The Bradford study area (Fig. 7.3.2) encompasses the metropolitan borough of Bradford, which includes surrounding centres like Keighley and Bingley. Bradford is the fourth largest metropolitan district in England with a population of 2.4 million and is located on the eastern foothills of the Pennine hills in West Yorkshire. Data from the Bradford monitoring sites are used in the 'Transferability of land use regression models in space and time' section to illustrate the transferability of LUR models. Forty sites in Thames Valley were identified in different locations (i.e. roadside, urban background, suburban, remote/rural) for deploying passive samplers (Ogawa, <http://www.ogawausa.com>) (Roosbroeck van et al. 2006) to measure concentrations of NO₂ over 2 weeks at three times (warm, cold, and one other period) during 2010. Values of NO₂ were averaged over all periods to create long-term (i.e. annual) concentrations of NO₂ for each

Table 7.3.1 Performance statistics used to evaluate LUR models.

Performance statistic	Description	Equation	Comments
R	Correlation coefficient	$\frac{\sum_{i=1}^n (O_c - \bar{O}_c)(P_c - \bar{P}_c)}{\sqrt{\sum_{i=1}^n (O_c - \bar{O}_c)^2 \sum_{i=1}^n (P_c - \bar{P}_c)^2}}$	This is the formula for the commonly used Pearson's correlation coefficient. Alternatively, Spearman's correlation is used where ranking is important or where the observed data are not normally distributed
R ²	Coefficient of determination	$1 - \frac{\sum_{i=1}^n (O_c - P_c)^2}{\sum_{i=1}^n (O_c - \bar{O}_c)^2}$	The proportion of variation in measured (observed) concentrations explained by the model. In other words, one minus the sum of squares of the residuals divided by the total sum of squares (proportional to the variance of the measured concentrations). This is not the same as (R) ² returned by some statistical software, which is simply the square of the correlation coefficient
MSE	Mean squared error	$\frac{1}{n} \sum_{i=1}^n (O_c - P_c)^2$	The mean of the squares of residuals. Also used as the numerator in MSE-based R ²
MSE-based R ²	MSE rescaled to be comparable to R ²	$1 - \frac{MSE}{\frac{1}{n} \sum_{i=1}^n (O_c - \bar{O}_c)^2}$	Equivalent to the coefficient of determination but differently written to be applied in model evaluation for comparison around the 1:1 line
RMSE	Root mean squared error	$\sqrt{\frac{1}{n} \sum_{i=1}^n (O_c - P_c)^2}$	The average error and is comparable to absolute concentrations
FAC2	Factor of 2	$\frac{1}{2} O_c \leq P_c \leq 2 O_c$	The percentage of predictions in the range of one half and double the observed concentrations
FB	Fractional bias	$2 \left(\frac{\bar{O}_c - \bar{P}_c}{\bar{O}_c + \bar{P}_c} \right)$	A measure of overall bias by comparing the mean of the observations with the mean of the predictions
IOA	Index of agreement	$1 - \frac{\sum_{i=1}^n (O_c - P_c)^2}{\sum_{i=1}^n [(O_c - \bar{O}_c) + (P_c - \bar{O}_c)]^2}$	The index is based on squared differences between predicted and observed values and it varies between 0 (complete disagreement) and 1

O_c , observed concentration; P_c , predicted concentration; \bar{O}_c , mean of observed concentrations; \bar{P}_c , mean of predicted concentrations.

measurement location. LUR models were developed in 36 ESCAPE areas for NO₂ using harmonized digital data to develop predictor variables. Further details of the measurements and models can be found in Cyrus et al. (2012), Eeftens et al. (2012a, 2012b), Beelen et al. (2013), and de Hoogh et al. (2013).

For the Thames Valley area, 80 different variables were created including information on distance to the nearest road, traffic flow on the nearest road, and circular buffers for road length, traffic intensity (the sum of road length multiplied by traffic flow on each road), low- and high-density housing, industry, population counts, and urban green space. For land cover variables, the pan-European CORINE data set was used (<http://www.eea.europa.eu>). Variables relating to roads were developed from a central data set (Eurostreets version 3.1 digital road network (1:10,000 resolution) derived from the TeleAtlas MultiNet) for the year 2008. Traffic composition was obtained in the United Kingdom from the Department of Transport. Road and traffic intensity variables were extracted in circular buffers of 25, 50, 100, 300, 500, and 1000 m reflecting the local influence of these sources on air pollution levels. Land cover variables were extracted in buffer distances of 100, 300, 500, 1000, and 5000 m. Buffer distances of 1000 m and more were included to reflect regional influences, not picked up by the smaller buffers.

An LUR model was developed for Thames Valley according to the procedure described in the 'Developing land use regression models' section (also see Box 7.3.1). Table 7.3.2 shows model development from the first stage (i.e. the initial strongest variable) to the final model, which includes three variables. Values of β represent the coefficients (i.e. 'weights') applied to each variable and values for the statistical significance are denoted by 'Sig. (p)'. Each model includes a constant (i.e. intercept) to represent 'background' concentrations; in other words, the constant is the value of NO₂ concentration at locations where there are assumed to be no detectable source emissions.

As shown in Table 7.3.2, the strongest predictor variable at stage 1 is 'HEAVYTRAFLOAD50' (i.e. the sum of the number of heavy goods vehicles multiplied by road length within 50 m) which explains approximately 67 per cent of the variability in measured concentrations of NO₂. At stage 2 a variable for road length within 500 m is added to the model which increases the adjusted R² to approximately 83 per cent. At stage 3 a variable for housing (HLDRES5000) is added to represent the diffuse emission from housing and minor roads otherwise not included in the model. At stage 4, the previously strongest variable (HEAVYTRAFLOAD50) is removed from the model ($p > 0.1$) and replaced by a similar

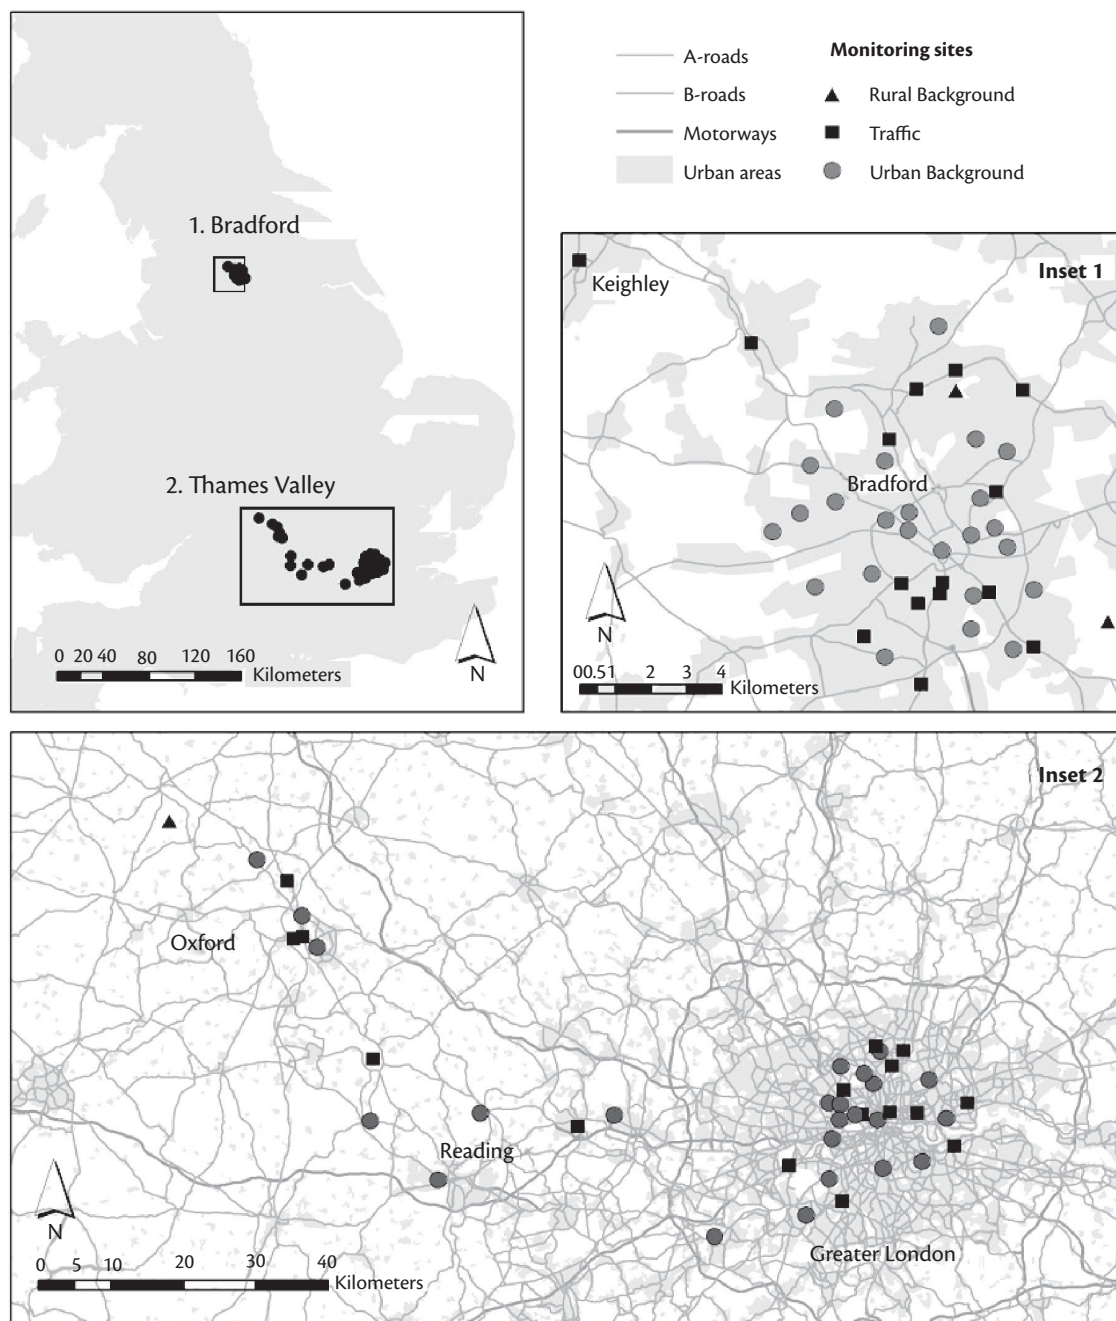

Fig. 7.3.2 Monitoring site locations for the Thames Valley and Bradford study areas.

Source: data from *Atmospheric Environment*, Volume 62, Cyrus, J. et al., Variation of NO_2 and NO_x concentrations between and within 36 European study areas: results of the ESCAPE project *Atmos*, pp. 374–390, Copyright © 2012 Elsevier Ltd and *Atmospheric Environment*, Volume 62, Eeftens, M. et al., Spatial variation of $\text{PM}_{2.5}$, PM_{10} , $\text{PM}_{2.5}$ absorbance and $\text{PM}_{\text{coarse}}$ concentrations between and within 20 European study areas and the relationship with NO_2 —Results of the ESCAPE project, pp. 303–317, Copyright © 2012 Elsevier Ltd.

variable for all traffic (TRAFMAJORLOAD50) rather than heavy vehicles alone (NB: there was very little difference in the explained variability of these two variables at stage 1: approximately 67 per cent); variables for heavy traffic and all traffic on major roads within 50 m buffers are highly correlated as indicated by high values of VIFs (> 10). As with most LUR models, the variables added at later stages tend to increase the adjusted R^2 by decreasing amounts, until no variable can add more than 1 per cent to the adjusted R^2 .

The final model (stage 4) includes three variables: traffic load within 50 m, road length within 50 m, and residential housing within 5000 m. Logically, road length within 50 m is an indicator of emissions from the nearest road(s), traffic load within 500 m is an indicator of the magnitude of traffic emissions in the wider area (i.e. beyond the nearest road), and housing within 5000 m represents emissions from domestic sources but may also represent traffic emissions from minor roads which are otherwise not included in the model. The model explains approximately 89 per cent of the

variability in monitored concentrations. The variables are associated with low values of VIF (i.e. < 2), values of statistical significance are all substantially less than 0.05.

Due to the relatively low number of sites available in the Thames Valley area, the ESCAPE NO₂ LUR model was evaluated using LOOCV. The LOOCV R² (as shown in Table 7.3.3) is the same (R² = 0.89) as for model development (R² = 0.89). Table 7.3.3 also shows some of the more informative of the summary statistics that are described in Table 7.3.1. Also included is the slope of the regression line (β) and 95 per cent confidence intervals associated with the regression fit. A good model performance will result in the lower and upper bounds of the confidence intervals intersecting with a value of 1.

Table 7.3.3 also shows performance statistics for Moran's I (Getis and Ord 1992) which is a measure of spatial autocorrelation in the model residuals. In the case of the Thames Valley model evaluation, Moran's I of 0.37 was returned indicating slight clustering of residuals, but this was not statistically significant (p = 0.71).

Figure 7.3.3 shows a comparison of predictions (x-axis) and measured values (y-axis). In the perfect model, all points would lie on the 1:1 line shown on the graph. The regression line represents the best-fit line for the model predictions. In essence, the closer the

best fit line lies to the 1:1 line then the better the fit of the model; the aim is for beta to have a value close to 1 and the constant to be small (i.e. $y = \beta_0 + X\beta_1$). As Table 7.3.3 shows, the slope of the regression line (measured NO₂ = 1.119 + (0.968 × LOOCV NO₂)) means the model evaluation is close to 1:1. As shown in Fig. 7.3.3 and via the summary statistics in Table 7.3.3 the LUR model appears valid for exposure assessment in Thames Valley.

Transferability of land use regression models in space and time

In order to develop LUR models it is necessary to collect/obtain both measured concentrations for the pollutant of interest and GIS predictor variables covering the entire study area. It may be possible to convert an LUR model developed for one pollutant to another (e.g. PM_{2.5} to NO_x) for the same area if the pollutants are known to be highly correlated, or there is an established method to convert between them (e.g. receptor modelling; Stedman et al. 2001). It may also be possible to transfer LUR models developed in one area to another in both space and time. This does, however, raise concerns about the 'transferability' of models due to differences in source emissions and geographical characteristics of the distribution of sources (i.e. urban form).

The transferability of LUR models in space and time is illustrated here with an example from the recent ESCAPE study. Some cohorts within this study were intended for a larger area than the study area (i.e. the area where measurements took place). In the United Kingdom, for example, the LUR models based on measurement in Thames Valley (see Fig. 7.3.2) were intended to provide exposure estimates for three cohorts, a proportion of which live or have moved outside the study area.

An analysis was undertaken to see if the Thames Valley LUR model for NO₂ could be applied to measurement sites outside the study area—transferability in space. Moreover, the timeline

Fig. 7.3.3 Predicted versus measured NO₂ concentrations from LOOCV.

Source: data from *Atmospheric Environment*, Volume 72, Beelen, R., et al., Development of NO₂ and NO_x land use regression models for estimating air pollution exposure in 36 study areas in Europe—the ESCAPE project, pp. 10–23, Copyright © 2013 Elsevier Ltd.

of cohorts (start-up, first follow-up, second follow-up, etc.) rarely coincides with the time period of the measurement data used to develop the LUR model. For example, the ESCAPE LUR model represents annual mean NO₂ concentrations for 2010, whereas EPIC Oxford, one of the cohorts in the ESCAPE study, started in 1993 and had follow-ups in 2001/2002 and 2007/2008. We therefore also had to assess how well the LUR model for 2010 predicts air pollution exposures going back in time—transferability in time. In order to investigate both these issues (space and time) we used monitoring sites from the Automatic Urban Rural Network (AURN; <http://www.airquality.co.uk>) covering the whole of the United Kingdom, measured over a long period (1994 to present), and independent from the model development.

Table 7.3.4 shows the performance statistics resulting from applying the Thames Valley model to the Bradford monitoring sites. The R^2 (0.42) is substantially reduced compared to the R^2 (0.89) from the within-area model evaluation (see Table 7.3.3). The other performance statistics further suggest that there are problems in transferring the Thames Valley model to Bradford. A mean squared error (MSE)- R^2 of zero and the equations of the regression line show that, when transferred, the model provides a poor fit around unity (i.e. 1:1). Because the correlations are moderate to good rather than poor it would still be possible to calibrate the model transfer if there were some monitoring sites (i.e. AURN) within the target area. Otherwise the Thames Valley model under-predicts concentrations of NO₂ in Bradford by approximately 13 micrograms/m³.

The analysis was extended to a national assessment of the transferability of the Thames Valley model in space and time. Table 7.3.5 shows the performance (R^2 , n) of the Thames Valley model applied to AURN sites located inside the Thames Valley area (i.e. the area within 10 km of the area encompassing the ESCAPE measurement sites) and by distance bands radiating from the edge of the study area, from 2010 (i.e. ESCAPE NO₂ measurement year) back to 1999. Fig. 7.3.4 shows the location of AURN sites and the distance bands radiating from the edge of the Thames Valley study

Table 7.3.4 Summary statistics from transfer of the Thames Valley model to Bradford measurement sites.

1999	0.616	23	0.584	16	0.442	20	0.149	12

area. The performance of the Thames Valley model at AURN sites within the study area is similar to that obtained in model evaluation (i.e. LOOCV shown in Table 7.3.3) for 2007–2010. For earlier years, model performance weakens (R^2 : ~0.55–0.62) but is still in the range of what modellers would deem to be ‘good’ performance. The Thames Valley model performance is weaker at sites outside the study area for more recent years (i.e. 2007–2010). Model performance is broadly similar back in time in the middle distance bands (i.e. >10–≤100km and >100–≤200 km) but is much weaker for earlier years for sites further away from the Thames Valley area. It must be borne in mind, however, that performance measures for earlier years were calculated on relatively few sites, which might raise concern about robustness of the assessment. Furthermore, direct comparisons between years should be treated with caution as the site list changes over time (e.g. some sites present in 1999 were no longer in existence in later years; new sites have been deployed in later years).

Discussion

The transferability of LUR models in space and time (back-extrapolation) is a relatively recent pursuit motivated by the needs of epidemiological studies.

Some studies have transferred models in space either from one city to another (i.e. as shown here for the transfer of the Thames Valley model to Bradford) or have evaluated national-scale models in specific locations. A National LUR model for Switzerland (Liu

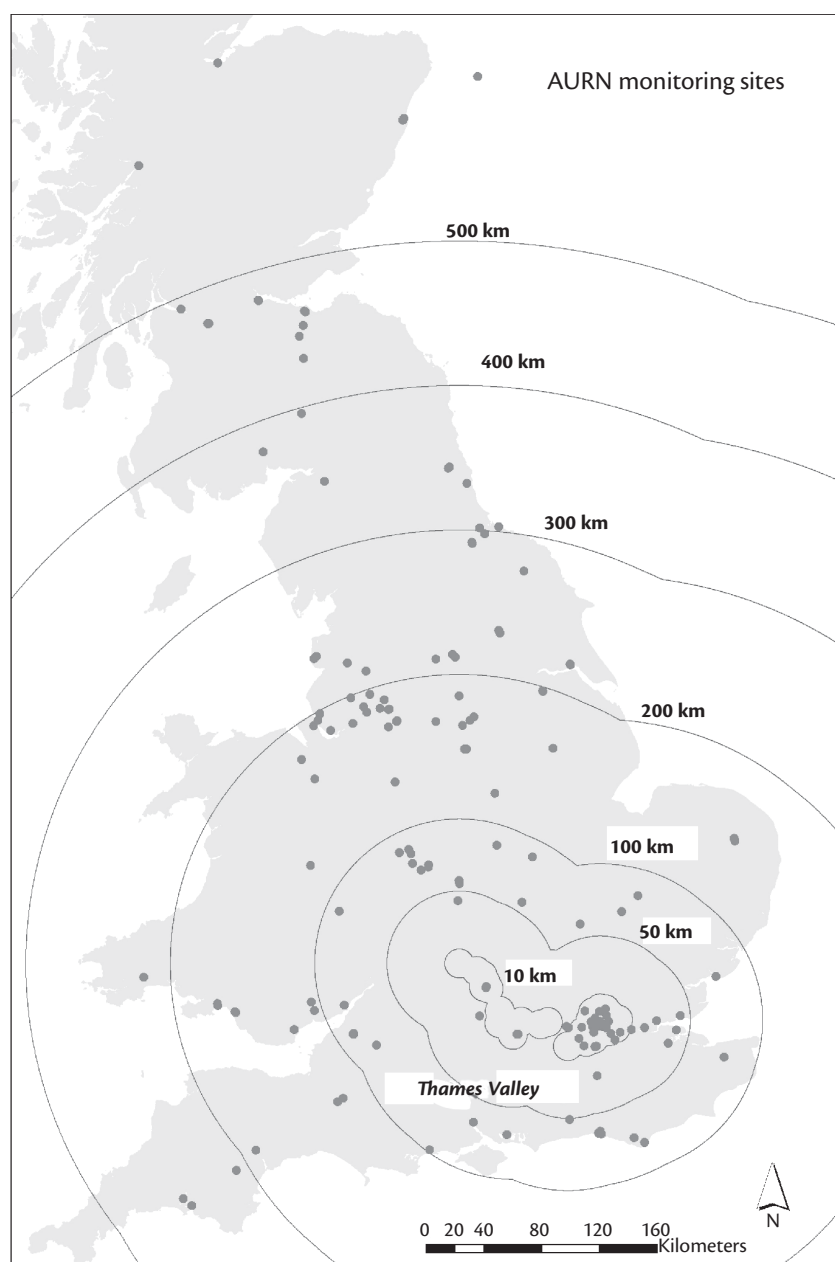

Fig. 7.3.4 Distance bands and location of UK routine monitoring sites

et al. 2012) performed well in back-extrapolation to the early 1990s (R^2 : ~0.80–0.84) but did not fit individual areas well (R^2 : ~0.02–0.61). A national LUR model ($R^2 = 0.73$) in Canada (Hystad et al. 2011) was shown to be much weaker in some areas when evaluated against independent city-specific monitoring sites (R^2 : ~0.18–0.60). It was suggested that differences in topography and meteorology led to weak model performance in some areas. Conversely, it was shown that one LUR model in the Netherlands (Eeftens et al. 2011) was sufficient to capture spatial variation in 1999/2000 and 2007, yielding model R^2 of 0.85 and 0.86, respectively, which may relate to fewer differences in topography and homogeneity of sources. Vienneau et al. (2010) showed that national models for

Great Britain and the Netherlands weakened when transferred but still provided satisfactory performance ($r^2 > 0.5$). Results of these assessments are mixed so care should be taken in transferring LUR models in space.

A few studies have transferred LUR models in time. An LUR model developed for 2007 NO_2 concentrations in Rome (Cesaroni et al. 2012) had strong linear correlation ($r = 0.83$) with measured NO_2 concentrations at the same monitoring locations ($n = 67$) 12 years earlier. In the Netherlands, LUR NO_2 models were transferred for 1999/2000 forward to 2007, and 2007 models back to 1999/2000; models slightly weakened when applied to other years but still explained 81 per cent and 77 per cent of the variation in

monitored concentrations of NO₂, respectively (Eeftens et al. 2011). In the United Kingdom, back extrapolation of four different 2009 NO₂ models to 1991 monitoring sites (i.e. independent sites not used in model development) yielded values of MSE-R² of ~0.52–0.55 (Gulliver et al. 2013).

It is clear that models tend to perform less well when transferred in space and time than their performance in the study area where they were developed, but performance may still be acceptable. It is important in all cases, however, to consider a range of performance statistics. Taking the correlation (e.g. R , R^2) alone might be misleading as model transfer may result in a large degree of under- or overprediction, as seen here in the example of applying the Thames Valley model to the Bradford measurement sites. It is advisable to produce a range of performance statistics and plot the predictions against observations. Where possible also look at performance by different site types and if applying models over large geographical areas look at the performance stratified by space (e.g. regions or distance bands). LUR is a powerful and relatively easy to apply tool for exposure assessment, but it must be applied so that models reflect the sources contributing to air pollution concentrations and should be evaluated with a rigorous set of performance criteria. Even an LUR model that performs well will only provide information about outdoor air pollution at the address. 'Dynamic' models that both account for time-weighted exposures in different microenvironments and are applicable to cohorts or population wide studies are not yet available.

Occupational health

David Koh and Tar-Ching Aw

Introduction to occupational health

The World Health Organization (WHO) estimated in 2007 that the global labour force (about 3300 million) was half of the world's population (WHO 2007a). The officially registered working population includes 60–70 per cent of the world's adult males and 30–60 per cent of adult females. Most people between the ages of 22 and 65 spend approximately 40 per cent of their waking hours at work (Leigh et al. 1997).

Occupational health, as defined by a joint committee of the WHO and the International Labour Organization (ILO), involves the 'promotion and maintenance of the highest degree of physical, mental and social wellbeing of workers in all occupations' (Forsmann 1983). This definition emphasizes the term health rather than disease, and further implies a multidisciplinary responsibility as well as a mechanism for the provision of health services for the working population. As practised today, the main components of occupational health practice are reduction of risks from exposure to workplace hazards, placement of workers with existing ill health or impaired function in jobs that will not pose an added risk to the individual or to others, and health protection and health promotion for those at work. In many countries, such activities extend beyond the worker to include provision of treatment and prevention for family members. For a summary of key points on occupational health see Box 7.4.1.

History and development

The Italian physician Bernardino Ramazzini (1633–1714) is often described as the 'Father of Occupational Medicine'. His publication in 1700, *De Morbis Artificum Diatriba*, was the seminal text in occupational medicine. Ramazzini stated that according to Hippocratic teaching, 'When you come to a patient's house, you should ask him what sort of pain he has, what caused them, how many days he has been ill, whether the bowels are working and what sort of food he eats' (Ramazzini 1713/1964). Following this citation, Ramazzini wrote: 'I may venture to add one more question: *What occupation does he follow?*' Ramazzini described many occupational illnesses that are still seen today, and the principles for their control.

The Industrial Revolution and occupational health

The major event that profoundly influenced the development of occupational health was the Industrial Revolution in the eighteenth century. Engineering and scientific innovations in the Western world, related to newly introduced industrial processes and the

setting up of factories, led to dramatic social changes. Previously, work was done mainly by craftsmen in rural cottage industries. The Industrial Revolution resulted in work being carried out in factories in urban centres.

Effects were seen both within the community, as well as in the individual worker. Family life was disrupted, with men leaving their families and moving to work in new industrial areas. In these new areas, health and social problems emerged, for example, poor housing and sanitation, alcoholism, prostitution, and poverty. Inside factories, individuals were exposed to long hours of work and uncontrolled occupational hazards, and the risk of accidents. Child labour and apprenticeship of young children were commonplace, and there was an absence of labour legislation.

As problems of industrialization grew, people of influence and political power campaigned to improve working conditions. Occupational health legislation appeared towards the end of the eighteenth century, and progressively developed to protect the health and rights of workers.

Today, the phenomena seen during the Industrial Revolution are being replicated in some rapidly developing nations. Even in industrialized nations, similar problems are still encountered by migrant workers and other deprived sectors of society.

Occupational health legislation

Many countries today have comprehensive occupational health legislation. For example, in the United States, the Occupational Safety and Health Act was passed by Congress in 1970. Its goal was to assure safe and healthy working conditions for working men and women. The UK Health and Safety at Work Act 1974, provided a broad legislative framework for the protection of workers. The European Union (EU) adopted a policy in 1989 on the 'Fundamental Social Rights of Workers', emphasizing the need for safety and health protection in the workplace, improvements in living and working conditions, and provision of social protection for workers. Over 180 countries belong to the ILO. This is a United Nations (UN) agency that produces and promulgates international labour standards, and promotes social justice and human and labour rights.

A historical development was the passing of legislation to ensure that employers do not discriminate against job applicants and employees with disabilities. One example of such legislation is the Disability Discrimination Act 1995 in the United Kingdom. The equivalent legislation in the United States is the Americans with Disabilities Act, 1990 (ADA). In 2006, the UN adopted a Convention on the Rights of People with Disabilities (ILO 2006a).

Box 7.4.1 Occupational health—key messages

- ◆ 2.3 million occupational and work-related deaths, 330 million non-fatal occupational accidents, and 160 million cases of work-related illnesses are estimated to occur annually.
- ◆ Workers form almost 50 per cent of the world's population, and are at risk of developing occupational, work-related, and general diseases.
- ◆ The risks from workplace exposures and work activities can be reduced via primary, secondary, and tertiary prevention.
- ◆ Promotion of health of the workforce can complement efforts to reduce exposure to hazards at work.
- ◆ Effective communication is a key factor in the management of occupational health issues.
- ◆ Occupational health practice has evolved to encompass environmental health considerations.

Occupational diseases, injury, and work-related ill health

The ILO reported that in 2008, 2.34 million people died from work-related accidents or diseases (ILO 2011). The majority (2.02 million) were caused by various types of disease, while 321,000 deaths resulted from work-related accidents. On average, more than 6300 work-related deaths occur every day. An analysis of the causes of work-related mortality revealed that 29 per cent were due to malignant neoplasms, 25 per cent were due to communicable diseases, 21 per cent were due to circulatory diseases, 14 per cent were due to occupational injuries, and 7 per cent were due to respiratory disease (ILO 2011).

Workplace hazards are responsible for a significant proportion of global morbidity. It has been estimated that 37 per cent of back pain, 16 per cent of hearing loss, 13 per cent of chronic obstructive pulmonary diseases, 11 per cent of asthma, 10 per cent of injuries, 10 per cent of lung cancers, and 2 per cent of leukaemias are related to work (Concha-Barrientos et al. 2004).

In total, work-related accidents and diseases have been estimated to result in a 4 per cent loss of the global gross domestic product. However, these statistics offer only a partial picture and most likely underestimate the true extent of the problem. This is because limited or no data for non-fatal occupational illness and injury are available from most countries.

Over 100 occupational diseases have been classified according to the tenth revision of the International Classification of Diseases and Related Health Problems (ICD-10), and the list is expected to grow with the current efforts in developing ICD-11. Occupational diseases are usually classified by the target organs affected, for example, respiratory, musculoskeletal, cardiovascular, reproductive, neurotoxic, skin and psychological disorders, or by effects, for example, hearing loss, occupational infections, and cancer.

Major types of occupational disease and injury

Occupational illness can affect virtually every organ system. Occupational diseases of the lung and skin are common since these organs have substantial surface areas in direct contact with toxic substances. Noise-induced hearing loss and musculoskeletal

disorders are among the most common disorders arising from physical factors in the workplace. Occupational cancer is a major concern because of the high mortality associated with many forms of cancer. Increasing attention has been paid in recent years to stress and work-related mental ill health, and diseases affecting the neurological, reproductive, and immunological systems.

Occupational lung diseases

The respiratory system is an easily accessible target organ for airborne toxic agents. Major categories of occupational lung disease include the pneumoconioses ('dust diseases' of the lungs), lung cancer, occupational asthma, chronic bronchitis and other effects of respiratory irritants, and occupational pulmonary infections. Silicosis is the most common form of pneumoconiosis worldwide. Exposure to silica occurs in a wide variety of occupations such as sandblaster, miner, miller, pottery worker, foundry worker, and workers using abrasives. In the United States, over 1 million workers are at risk of developing silicosis each year. From 1968 to 2005, silicosis was recorded as the underlying cause of death in over 7000 death certificates (Centers for Disease Control and Prevention 2008). Exposure to silica dust in the construction of the Hawk's Nest tunnel in West Virginia (1930–1931) was responsible for the highest recorded number of silicosis deaths from a single construction activity in the United States (Cherniak 1986). The International Agency for Research on Cancer (IARC) has classified crystalline silica as a known human carcinogen (IARC 1997).

Asbestos is another important cause of lung diseases that include mesothelioma, lung cancer, and asbestosis (a form of progressive pulmonary fibrosis). Historical asbestos consumption per head of population is related to an increase in asbestos-related diseases (Lin et al. 2007), and asbestos is responsible for over 100,000 deaths per year worldwide (Takala 2003). It has been estimated that there will be more than half a million disability-adjusted life years globally due to asbestos-induced malignant mesothelioma (Driscoll et al. 2005). Given the long latency, the future burden of mortality resulting from asbestos will be substantial even if all future exposure were to be eliminated completely.

Bronchial asthma affects about 300 million people worldwide, with an increasing prevalence every decade. More than 10 per cent of the population in developed countries are affected (Braman 2006). Population-based estimates suggest that 10–25 per cent of new-onset asthma cases in adults are work related (Kogevinas et al. 2007). In some jurisdictions, occupational asthma has become the most prevalent occupational lung disease, exceeding silicosis and asbestosis. Even so, prevalence studies of occupational asthma usually underestimate the number of affected workers because these workers tend to quit jobs where they suffer such symptoms, although their asthma symptoms and signs may continue even after leaving work.

Many gases, fumes, and aerosols are directly toxic to the respiratory tract, causing acute inflammation. Examples include soluble irritants, for example, hydrogen chloride, ammonia, and sulphur dioxide, which produce effects in the eyes, nasopharynx, and large airways. Less soluble irritants (e.g. nitrogen dioxide, ozone, phosgene) produce few upper-respiratory symptoms, but following high exposure can cause delayed pulmonary oedema.

Occupational cancer

Occupational carcinogens include chemical substances, for example, benzene and asbestos; physical hazards, for example, ionizing

radiation; and biological hazards, for example, viruses. It is estimated that approximately 16 million workers in the EU are exposed to carcinogens at work. The most common cancers due to these workplace exposures are cancers of the lung, bladder, skin, and liver.

Occupational cancer accounts for about 4–20 per cent of all cancers in developed countries. Variability in the estimates arises from differences in data sets used and assumptions applied. The most commonly accepted estimate is 4 per cent with a plausible range, based on the best quality studies, being 2–8 per cent. However, if one considers only the adult population in which exposure to occupational carcinogens occurs almost exclusively, the proportion of cancer attributed to occupation would increase to about 20 per cent among those exposed (Pearce et al. 1998).

Occupational skin disorders

Skin disorders are among the most commonly reported occupational diseases. The annual incidence rate for work-related skin disease in the United Kingdom is 136/100,000 (Health and Safety Executive (HSE) 2011a). The most common occupational skin disorder is irritant contact dermatitis. Although skin disorders are relatively easily diagnosed, occupational skin diseases are believed to be under-reported, so that the actual rate is many times higher than officially reported (European Agency for Safety and Health at Work 2008). Occupational skin disorders are unevenly distributed between industries. Florists, hairdressers and barbers, metal workers, and maintenance fitters are occupations at risk. In general, a worker in agriculture, forestry, fishing, or manufacturing has a much greater risk of developing a work-related skin disease compared to a worker in other industries. This is likely to be due to their exposure to a wider range of substances known to be irritants or allergens.

Occupational infections

Much attention about infectious diseases has focused on healthcare settings, although infections can be transmitted in other work places, such as research laboratories and animal processing facilities. In healthcare settings, awareness has grown about the risk of infection from hepatitis B, the human immunodeficiency virus (HIV), and tuberculosis (*Mycobacterium tuberculosis*). Needlestick injuries accounted for about 40 per cent of hepatitis B and hepatitis C infections and 4.4 per cent of HIV infections in healthcare workers (Pruss-Ustun et al. 2005). An increased risk of HIV infection has been shown to exist in settings in which workers may be exposed to blood or body fluids (National Institute for Occupational Safety and Health (NIOSH) 1996).

Transmission of *M. tuberculosis* is a recognized risk in healthcare facilities. After years of declining incidence rates, multidrug-resistant tuberculosis has re-emerged as a major occupational and public health problem globally (Morens et al. 2004; Shah et al. 2007; WHO 2007b).

Emerging infectious diseases also pose a risk to healthcare workers. One example is severe acute respiratory syndrome (SARS), caused by a novel coronavirus. In the 2003 worldwide outbreak of SARS, 20 per cent of patients were healthcare workers (Koh et al. 2003). Concerns about the risk of infection among healthcare workers also apply to a range of other infections such as respiratory syncytial virus and influenza A (H1N1).

Infectious diseases can be especially prevalent in developing countries, resulting in higher risks for workers in these countries.

Some of the infections result directly from the work, while others are indirectly related to work. Examples include vector-borne diseases, for example, malaria, dengue haemorrhagic fever, Lyme disease, and anthrax; water and food-borne diseases resulting from poor sanitation and inadequate potable water, for example, cholera and typhoid; and zoonoses among veterinarians, farmers, agricultural and forestry workers, for example, leptospirosis and rabies.

Occupational reproductive disorders

The overall contribution of occupational exposures to reproductive disorders is not known because there has been scant research in this area. Few studies are available especially on physical and biological agents that may affect fertility and pregnancy outcomes in humans.

Occupational exposure to chemical agents such as lead (Pb) and the pesticide dibromochloropropane (DBCP) have been documented to cause testicular effects with resultant reduction in sperm count. Pb can also cross the placenta in a pregnant woman to cause adverse effects in the developing fetus. Other substances associated with documented adverse reproductive outcomes include metal compounds (e.g. methyl mercury), solvents (e.g. carbon disulphide), oestrogenic agents, anaesthetic gases, antineoplastic drugs, carbon monoxide, ethylene oxide, ethylene glycol ethers, polychlorinated biphenyls, and physical agents (e.g. ionizing radiation).

Occupational exposures can cause a wide range of reproductive disorders in both males and females (Kumar 2004; Jensen et al. 2006). Effects of exposures in males include reduced sperm count, aberrant sperm shape, altered sperm function; and lowered hormone levels or libido. Exposures in females may cause menstrual cycle irregularities, infertility, chromosomal aberrations, reduced breast milk production, early onset of menopause, and suppressed libido.

Reproductive disorders also include adverse effects on the offspring of the exposed worker. Potential fetal and developmental effects from maternal exposures include preterm delivery, fetal loss, prenatal death, low birth weight, altered sex ratio of live births, congenital malformations, childhood malignancies, and neurobehavioural disorders in the offspring.

Occupational noise-induced hearing loss

High levels of occupational noise are a persistent problem all over the world. In the United States, up to 30 million workers are exposed to hazardous noise levels at work (NIOSH 2011). In Germany, 12–15 per cent of the workforce are exposed to hazardous noise levels (Concha-Barrientos et al. 2004). In most developing countries, noise-induced hearing loss (NIHL) is one of the most commonly reported occupational disorders. Twenty per cent of workers in the EU indicate exposure to high levels of noise for at least half of their working hours. Noise exposure is especially high in the manufacturing and construction industries.

Industries such as manufacturing, mining, construction, transportation, agriculture, and the military are at the highest risk for NIHL. In developed countries, increasing awareness has led to greater implementation of protective measures, whereas in developing countries, industrialization may herald an increase in exposure to noise (Loney and Aw 2012).

Occupational traumatic injuries

These injuries include such events as amputations, fractures, severe lacerations, eye losses, acute poisonings, and burns. In 2008, approximately 317 million workers were injured in accidents at

work that resulted in an absence of 4 days or more from work. This translates to an annual accident incidence of 10,600 per 100,000 workers, or 850,000 injuries per day. For every fatal accident there are another 500–2000 injuries, depending on the occupation (ILO 2002). In Great Britain, the rate of non-fatal major injuries reported in 2005 to 2006 was 100.3 per 100,000 workers. European Statistics at Work reported about 4.7 million accidents at work in the EU which resulted in 3 or more days away from work in 2001, and about 4900 fatal accidents at work (Eurostat 2010).

Work-related diseases

Work-related diseases are diseases in which occurrence may be associated with workplace factors, but these need not be the only risk factor in each case. They occur more commonly than pure ‘occupational diseases’, and the term is also used to refer to aggravation of a pre-existing medical condition by workplace factors. While prevention of occupational diseases is possible by the elimination of the workplace hazard, work-related diseases cannot be entirely prevented by only addressing occupational hazards. Common work-related diseases include hypertension, ischaemic heart disease, psychosomatic illnesses, musculoskeletal disorders, and non-specific respiratory disease. Two examples are given in the following subsections.

Work-related musculoskeletal disorders

In developed countries, acute and chronic work-related musculoskeletal disorders are a major cause of morbidity affecting workers. The term ‘work-related musculoskeletal disorders’ encompasses a range of conditions from back pain, upper and lower limb disorders, neck and shoulder symptoms, hand–arm vibration syndrome (HAVS), carpal tunnel syndrome, repetitive strain injury, and other effects on the musculoskeletal system. Musculoskeletal disorders, in particular low back pain, rank alongside mental and behavioural disorders as major causes of long-term sickness absence in the United Kingdom. For 2010/2011, around three-quarters of new cases of work-related conditions in the United Kingdom were due to either musculoskeletal disorders or stress, depression or anxiety (HSE 2012). In the EU, musculoskeletal problems were the most commonly reported work-related health problem accounting for 60 per cent of reports (European Commission 2010). In the United States, musculoskeletal disorders account for 34 per cent of all non-fatal occupational injuries and illnesses involving days away from work (NIOSH 2007). This is also true in many other developed countries. More than half of the working population experience low-back injury at some time in their working career.

Stress-related ill health

Job stress has been defined as the ‘harmful physical and emotional responses that occur when the requirements of the job do not match the capabilities, resources or needs of the worker’ (NIOSH 1999). NIOSH reports that in the United States:

- ◆ 25 per cent of employees view their jobs as the main stressor in their lives.
- ◆ 75 per cent of employees believe the worker has more on-the-job stress than a generation ago.
- ◆ Problems at work are more strongly associated with health complaints than any other life stressor—more than even financial or family problems.

- ◆ Workers who take time off work because of stress, anxiety, or a related disorder will be off the job for about 20 days.

Individual and situational factors, such as balance between work and family life, social support, individual outlook, and personality can affect the likelihood of developing stress. However, working conditions often play a significant and sometimes major role in the causation of stress.

Workplace stress-related hazards consist of factors in both work content as well as context (Leka et al. 2003). Work content encompasses job content (e.g. meaningless, unpleasant tasks), workload (under- as well as overload) and working under time pressure, work schedules (e.g. long, unsociable, inflexible working schedules), degree of participation in decision-making, and lack of control of work. Work context includes concerns about career development, status and salary, the individual’s role in the organization, issues relating to interpersonal relationships, the organizational culture/climate, and conflict or lack of support in the home–work interface.

The clinical manifestations of occupational stress are indistinguishable from stress caused by non-work factors. Stress can present as emotional lability, anxiety, depression, insomnia and even attempts at suicide. Adverse health outcomes of job stress are wide ranging, from increased risk of cardiovascular disease, musculoskeletal symptoms, impaired immune function, and gastrointestinal disorders, for example, peptic ulcers and irritable bowel syndrome (Barbara et al. 2004). The impact of workplace stress on an organization may include a decrease in work commitment, reduced productivity, lowered staff morale and increase in absenteeism, increasing staff and customer complaints, and a poor public image for the company.

General diseases affecting the working population

General diseases prevalent in every community include infections such as HIV/AIDS, tuberculosis and malaria, or non-communicable diseases and lifestyle-related diseases, for example, diabetes mellitus, cardiovascular disease, cancer, and malnutrition. These diseases may not be directly caused by occupational exposures, but can invariably affect work productivity. Workplace factors can also influence the progress and prognosis of these diseases.

Estimates of costs and economic loss

Total economic losses due to occupational injuries and illnesses are large. The ILO estimated that overall economic losses from work-related injuries and illnesses in 1997 were approximately 4 per cent of the world’s gross national product (GNP). According to recent estimates, the cost of work-related health loss and associated productivity loss may amount to several per cent of total GNP of a country. For example, the HSE has estimated the cost of occupational illness and injury to the British economy to be £14 billion in 2009–2010 (HSE 2011b). The main contributors to these estimated costs are provision of medical care, rehabilitation and compensation, loss of working days (over 25 million days a year) and therefore productivity for the organization and loss of income for the affected individual, and associated costs of concurrent damage to property and equipment. There are also non-financial ‘costs’ from pain, grief, and suffering.

In the United States, the direct cost of the most disabling workplace injuries and illnesses in 2008 was estimated to be US\$53

billion, with substantial additional indirect costs ranging up to 4.5 times the direct costs, and the indirect costs ranging from US\$137.4 to US\$229 billion (Occupational Health and Safety Administration 2012).

Under-recognition of occupational ill health

Although recording of workplace injuries is reasonably accurate in most developed countries, this is not so for occupational illnesses where there are substantial under-estimates of actual cases. One explanation for this is the inherent difficulty in diagnosing occupational diseases and in establishing cause-and-effect relationships. The link between occupation and disease may sometimes be unclear, because most occupational diseases are not distinct clinically and pathologically from diseases associated with non-occupational aetiologies. For example, skin cancer caused by polycyclic aromatic hydrocarbons is similar in appearance to that caused by excessive exposure to sunlight. Similarly, solvent-induced encephalopathy may easily be confused with effects of advancing age. Only for a very limited number of diseases, for example, mesothelioma (caused by asbestos), and angiosarcoma of the liver (caused by vinyl chloride monomer) is the causal association between occupational exposure and disease readily established initially primarily on clinical grounds, and mainly based on a good occupational history documenting exposure.

Another cause of the under-recognition of occupational disease is that the majority of chemicals in commerce have never been fully evaluated in regards to their potential toxicity. Only a small percentage of the approximately 80,000 chemicals currently used in industry have been screened for toxicity. Such toxicity testing often concentrates primarily on high-dose, acute effects and on the long-term cancer risk. Toxicity testing for reproductive, neurological, immunological, and other adverse effects remains quite limited.

The long latency which typically elapses between occupational exposure and onset of illness is a third factor which may obscure the occupational aetiology of chronic disease. For example, occupational cancers rarely appear within 10 or even 20 years of first exposure to a carcinogen. Similarly, chronic neurotoxic effects of solvents may become evident only after decades of exposure. In such instances, it is unlikely that the worker will be diagnosed as having a disease of occupational origin.

Lack of awareness among health practitioners about the hazards found at work is a fourth cause of underestimation of occupational disease, reflecting the fact that most physicians are not adequately trained to suspect work as a cause of disease. With competing demands for time in the medical curriculum from an increasing number of disciplines and subject areas, most medical schools now only allocate limited time to teaching medical students to take a proper occupational history, to recognize symptoms of common industrial toxins, or to recall known associations between occupational exposures and disease. In the United Kingdom, there has been a progressive decline in the total number of hours allocated for occupational medicine in medical schools (Wynn et al. 2002).

Compounding a lack of medical awareness is the limited ability of many workers to provide an accurate report of their exposures. Workers may have had multiple toxic exposures in a variety of jobs over a working lifetime. In most countries, there are no requirements to inform workers of the hazard of the materials with which they work. In the United States, employers' reporting requirements remain limited under the Hazard Communication Standard and

state right-to-know laws. In many instances, a patient may not know or may not be able to remember all his or her past occupational exposures.

Finally, given the potential financial liability associated with the finding that a disease is of occupational origin, employers may be reluctant to recognize the work-relatedness of a disorder, especially in cases where personal habits or non-occupational pursuits are possible contributory factors. Since employers are often in the best position to recognize causal associations between workplace exposures and disease, this conflict of interest represents an obstacle to obtaining accurate estimates of the burden of occupational illness.

The changing work and health landscape

The global economy has expanded rapidly in the past few decades, but many of the estimated 3.5 billion workers in the world (China alone has a labour force of over a billion workers) continue to be employed in conditions which do not meet international health and safety standards and guidelines. These workers are exposed to high levels of dust, dirt, noise, toxic chemicals, and biological substances. Their health and livelihood, and sometimes their lives are at risk. In developed countries where there has been some success in the control of exposure to chemical and physical hazards, work stress and work-related musculoskeletal disorders have become major causes of ill health and sickness absence.

Globalization has reshaped the world with the introduction of new materials and procedures, advances in technology, improved communication tools, and greater flexibility in responding to production demands. However, the rapidly changing working conditions, new employment patterns and evolving labour relations can also pose challenges to the protection of workers' health. New global health threats have also emerged, such as the risk of epidemic and pandemic diseases (e.g. SARS and influenza A (H1N1) infection). These infections have affected occupational groups from healthcare workers to farmers. Global spread of infection has been facilitated by ease of international travel and increasingly porous health borders.

Other pressing concerns which impact the health of workers are international and internal migration of workers, a growing informal sector (where defined terms of employment and workers' benefits may be weak or non-existent), and discrimination at the workplace. These are often associated with unhealthy, unsafe, and unfair working conditions.

Despite the existence of protective legislation in many countries, the burden of injury and illness on workers remains significant. There is a need for international coordination of occupational health protection for workers, given the increasing globalization of the world economy. Several initiatives have been proposed to address this issue. This includes the harmonization of health, safety, and environmental standards in a way that does not unfairly impose a competitive disadvantage on the newly industrialized nations. Governments and multinational corporations must be prepared to share advances in control technology, expertise, and resources. Instead of allowing industries to manufacture products in other countries when these are banned for use in their own country, governments in developed nations could provide incentives for their industries to develop and export safer products and technologies. At a minimum, international systems should be established to ensure complete notification of potential hazards, including labelling the contents of raw materials and products.

Special populations of workers

Workplace hazards affect some worker populations disproportionately, for example, those in developing nations, child labourers, women employees, and impaired workers. These populations are especially vulnerable because of the interaction between their work roles and broader roles in society, as well as by their particular exposures in the workplace.

Workers in developing nations

More than 80 per cent of workers in the global workforce are from the developing world (Rosenstock et al. 2005). Workers' health should be viewed in the context of national development. Occupational health policymakers in many nations must consider a balance between adverse impacts on workers' health and the economic advantages of rapid development by allowing foreign investigators access to low-cost labour and weak labour protection provisions.

The relationship between workers' health and development is complex. For example, workers in many developing countries may be affected by poor nutrition or endemic diseases, such as malaria, in which work may aggravate the condition, or which make the worker more susceptible to the effects of workplace exposures. Workers in these countries also generally have lower educational backgrounds and are often inadequately trained to handle the new technologies and potential hazards. There may be high turnover with little management investment in worker training.

Working conditions in tropical developing countries (as in South East Asia), and countries with desert environments (as in the Middle East and North Africa) may present special hazards because of climatic conditions, building ventilation design, and equipment and production facilities. The importation of production equipment from developed countries can pose some difficulty with the availability of replacement parts and service. The machinery could be pre-owned or dated and possibly considered obsolete for use in the developed countries, while new and safer equipment may be unavailable or too expensive for developing countries.

The social organization of work in developing countries also affects workers' health. In addition to the large number of workplaces with a small number of workers, large proportions of the workforce work in the 'informal' sector. This sector consists of small, often home-based businesses that have no government registration and oversight. For example, recent estimates of the proportion of informal non-agricultural employment were about 58 per cent for Latin America and 75 per cent in sub-Saharan Africa. The informal economy accounts for 90 per cent of women working in non-agricultural sectors in India and Indonesia, and 95 per cent in Benin, Chad, and Mali (Rosenstock et al. 2005).

Finally, countries of the developing world may have access to advanced industrial technologies from the developed world, but they have little in the way of legal or administrative infrastructure to control the adverse impacts from these new technologies on the workforce. Even if developing countries adopt standards and legislation from more developed nations, there is often a shortage of trained personnel to recognize and manage workplace hazards.

Child labour

The ILO estimates that the global number of child workers is 215 million, with a large number involved in hazardous work (IPEC

2012). Child labour has become an important issue because the children are vulnerable to exploitation in the workplace and may be denied basic human rights, such as decent wages or access to education. Poverty is the primary reason why children work. Poor households need the money, and children in employment can contribute to family income. Unfortunately, if the family has a tradition of engaging in a hazardous occupation, it is likely that the children will continue in the trade.

Children in hazardous occupations are at greater risk of suffering ill effects than adult workers. They may have greater exposure to hazards than adult workers in the same occupation because children tend to be given the most menial jobs, which can involve higher exposures to toxic substances. Children are more susceptible to the same hazards faced by adult workers because they differ from adults in their physical, physiological, and psychological characteristics. Children using hand tools designed for adults run a higher risk of fatigue and injury. Personal protective equipment (PPE) designed for adults do not fit children, and therefore do not provide adequate protection. Furthermore, children may not be as aware as adults of workplace dangers, or as knowledgeable of precautions to be taken at work. Children are also more vulnerable to psychological and physical abuse than are adults, and suffer deeper psychological damage when they are denigrated or bullied.

The International Programme on the Elimination of Child labour (IPEC 2011) launched in 1992 was aimed at the elimination of child labour, giving priority to its worst forms. The 'worst forms' comprise all forms of slavery or practices similar to slavery; the use, procurement, or offering of a child for prostitution or production of pornography; the use, procurement, or offering of a child for illicit activities; and work which is inherently likely to harm the health, safety, or morals of children. Withdrawing children from the worst forms of child labour requires improved legislation and enforcement, improved methodologies for identifying the children, rehabilitation of the children, provision of viable alternatives to the children, and raising awareness at all societal levels.

The efforts of IPEC in the elimination of child labour are beginning to pay off, with a decline in the proportion of child labourers. Unfortunately, the rate of child labour continues to be disparately high in sub-Saharan Africa (ILO 2006b).

Women workers

Women in many countries of the world are often at a disadvantage compared to men in various spheres of society. As a result, gender issues have traditionally lacked visibility, and this includes women at work (WHO 2011).

About 42 per cent of the global workforce is female (Messing 2006). There is significant interplay between women's roles in society, socioeconomic condition, and occupation. Women's roles in traditional societies are defined in relation to child bearing and upbringing of children and responsibility for the care and comfort of the family. Paid employment of women has increased in most countries, but this has led to a conflict between the necessity to be at work and women's traditional home and family responsibilities. In many societies, early marriage, repeated pregnancies, large families, low educational status, and poverty all disproportionately impact on women workers (Loewenson 1999). The dual roles of women as workers and unpaid caregivers is especially challenging for sole-support mothers, who comprise 20–30 per cent of households worldwide.

Employment of women in most societies is characterized by occupational segregation, under-employment (often involved in doing seasonal and part-time work below their level of education), and barriers to advancement. Occupational segregation means that women tend to be clustered into a small number of occupations while being under-represented in most others (Stellman 1999). For example, professional women tend to be in teaching, nursing, and other healthcare specialties. In manufacturing, women tend to have jobs in assembly and small machine operations. Women in developing countries tend to be employed in sectors such as agriculture, textiles and clothing, food processing, and social services (Loewenson 1999). Compared with men, women work for smaller industries or organizations, have less opportunity for work control, and face the psychological demands of people-oriented or machine-paced work (Paltiel 1998). Women are more likely to work in the informal sector, in specific types of informal work such as domestic work, street vending, and sex work, with their accompanying low social status and lack of legislative protection. While many countries have enacted laws prohibiting gender discrimination, some countries still have formal restrictions on women's employment. Gender differences are also observed in the rates of occupational injuries and illnesses, but these differences are primarily because of differences in the conditions of work or exposures, rather than due to genetic differences (Stellman 1999).

Impaired workers

A large proportion of individuals with disabilities are in the working age group, and they are able to make constructive contributions in the workplace despite physical impairment. Legislation in some countries prohibits employers from discriminating against individuals with disabilities, and encourages employers to make reasonable accommodation for those with a known impairment.

France and Germany impose quotas on enterprises to employ a certain percentage of disabled people. India and Japan use employment promotion measures to ensure workplace accessibility and provide employment services in the form of job placement agencies. Singapore provides tax reductions as a financial incentive to compensate employers for any financial burden resulting from the employment of disabled people.

Reasonable accommodations are changes made to the work environment, job responsibilities, or conditions of work that provide opportunities for workers with special needs to perform essential job functions. These measures may include technical assistance devices; customization, including PPE and clothing; and changes to processes, location, or timing for essential job functions.

The chemical company DuPont showed that employees with disabilities perform as well as or better than comparable employees with no disabilities. Additional adjustments in the workplace were required by only 4 per cent of disabled people of employable age (ILO 2007a).

Migrant workers

There are an estimated 150–190 million migrants in the world—2 per cent of the world's population—including migrant workers, refugees, asylum seekers, and permanent immigrants. The number has increased dramatically with globalization. The vast majority of this migration is from developing to developed countries. Three-quarters of all migrants lived in 28 countries in 2005, with

one in five migrants living in the United States. Many migrants move to seek work.

According to the UN, 'migrant workers' are people who are to be engaged, are engaged, or have been engaged in remunerated activities in a State of which they are not nationals (UN 1990). Some migrant workers stay permanently in their new countries, while many return to their original homes after working for a period of time. The latter are strictly not true migrants, as they may have intentions of returning to their home countries after a period of gainful employment in a foreign land. Hence a more appropriate term for this group of workers is 'expatriate workers'.

Expatriate workers are a particularly vulnerable population for many of the same reasons that were described for workers in developing countries, for example, they may be affected by poor nutrition and endemic diseases, they often have lower educational backgrounds, and they are inadequately trained to deal with potential work hazards. This is especially true for expatriate manual workers. Many face additional obstacles because they do not speak the language of the host country adequately. They are often not familiar with local health and safety practices and regulations. The accommodation available for them can be temporary and often crowded with limited shared facilities and restricted access to medical care and other social services. Expatriate workers may encounter racism, xenophobia, and exploitation because they do not have full legal status or awareness of their rights in the host country (Holmes 2006; McKay et al. 2006).

Shift workers

Shift work and irregular work hours have increased significantly among those who are employed. The ILO found that 20 per cent of workers worldwide put in more than 48 hours of work a week, often earning only a bare minimum wage (ILO 2007b). A similar proportion of workers in the EU countries engage in shift work or night work (Eurostat 2010). The recent evaluation by the IARC regarding shift work and breast cancer indicating shift work that involves circadian disruption as probably carcinogenic to humans (Group 2A carcinogen) poses a challenge for occupational health and public health advice and intervention (IARC 2010). This finding has implications for occupational groups as varied as air crew, journalists, physicians, laboratory technicians, and telephone operators (Weiderpass et al. 2011).

Assessing the risk of work

Health protection begins with an assessment of risk. Risk assessment is a structured and systematic procedure that is dependent upon the correct identification of hazards and an appropriate estimation of the risks arising from them (HSE 1995). The purpose of risk assessment is to ensure that a valid decision can be made for measures necessary to control exposure to substances hazardous to health arising in the workplace. Risk assessments are legal requirements in many countries. It can be a qualitative or quantitative process.

Expertise, effort, and detail required for risk assessment depends on the nature and degree of risk, and the complexity of the work process. Adequate controls are determined based on several factors: the toxicity of substances, numbers exposed, acceptability of risk, legal requirements, costs, and availability of control measures.

Hazard and risk

In occupational health practice, an understanding of the difference between the terms ‘hazard’ and ‘risk’ is essential.

Hazard refers to a substance, agent, or physical situation with a potential for harm in terms of injury or ill health, damage to property, damage to the environment, or a combination of these. Hazards can be physical, chemical, biological, ergonomic, or psychosocial in nature.

Physical hazards include exposure to extremes of temperature, light, noise, vibration, electricity, and radiation. Chemical hazards cover a range of organic (aliphatic or aromatic) and inorganic chemicals. Biological hazards are those due primarily to infectious organisms (e.g. viruses, bacteria, rickettsia), and also prions and proteins. Ergonomic and mechanical hazards result from poor design of work stations and disorganized systems of work, and psycho-social hazards are those that contribute to and cause workplace stress. Hazard identification is the process of recognizing that a hazard exists and defining its characteristics.

Risk relates to the likelihood of the harm or undesired event occurring, and the consequences of its occurrence. It is the probability that the substance or agent will cause adverse effects under the conditions of use and/or exposure, and the possible extent of harm. It is thus a function of both exposure to the hazard and the likelihood of effects on health from the hazard. Extent of risk covers the population that might be affected by the risk, the numbers exposed, and the consequences.

Risk assessment

Risk assessment is the process of estimating the magnitude of risk, and deciding if the risk is tolerable or acceptable. A tolerable risk may not always be acceptable. It merely refers to a willingness to live with a risk to secure certain benefits, and in the confidence that the risk is being properly controlled (Sadhra and Rampal 1999). The levels of tolerability of risk are different for different countries, and in different working populations and the general public. The views on tolerability depend to a large extent on the populations that might be affected by the risk.

Risk assessment and risk management must take into account both routine and non-routine activities and conditions, including foreseeable emergency situations. Hazards that are intrinsic to these situations, or generated by such activities should be recognized. Exposed people should be identified, including non-employees and those who are susceptible and therefore at higher risk because of illness or other medical conditions. Existing control measures, if any, need to be evaluated.

The health risks from the hazards should be determined and assessed, and a decision made on whether the risk is acceptable or tolerable. Unacceptable risks have to be eliminated or reduced with new or improved control measures, and their effectiveness monitored. Such a process requires a team effort, involving the workers themselves as well as personnel with the relevant expertise. It is important to inform workers of the hazards, risks, and appropriate measures that have been and can be taken to protect them.

The steps for risk assessment for chemical, biological, ergonomic, and psychosocial hazards may differ, as illustrated by the following examples. The assessments for chemical or physical exposures are generally more objective and precise than the assessment for

psychological stressors. As an example, an initial assessment for a chemical exposure might include the following steps:

1. List substances in the area to be assessed.
2. Determine which substances are actually used, and in what quantities, and the frequency and duration of use.
3. Evaluate workers’ concerns.
4. Assess the tasks of workers, their exposure, and methods of handling.
5. Obtain suppliers’ data sheets.
6. Evaluate data sheets.
7. Inspect places where the substances are handled.
8. Evaluate method of control.
9. Perform environmental monitoring for the chemical if needed.
10. Decide on acceptability or tolerability of risk, and if further control measures are needed.

The assessment of psychosocial factors at work is more complex. It may include the evaluation of organizational dysfunction, work conditions, as well as a study of indicators such as sickness absence, staff turnover, and measurement of stress-related illness among employees. Possible work stressors are poor design of tasks, aggressive management style, inadequate interpersonal relationships, unclear work roles, limited career prospects, and adverse environmental conditions at the workplace. The extent of work stress can be assessed by use of validated questionnaires administered to staff; for example, the General Health Questionnaire (Jackson 2007), the Finnish Occupational Stress Questionnaire (Elo et al. 1992), or the NIOSH Generic Work Stress Questionnaire (NIOSH 2008).

Assessing exposure

Environmental monitoring

Environmental or ambient monitoring in the workplace is undertaken to measure external exposure to harmful agents. The monitoring is to ensure that exposure is kept within ‘permissible levels’ so as to prevent the occurrence of disease. The concept of permissible levels assumes that for each substance there is a level of exposure at or below which the exposed worker does not suffer any health impairment.

Permissible levels or occupational exposure limits

These are standards that have been set for commonly encountered physical, chemical, and biological hazards in workplaces. There are variations in exposure limits from different countries and different agencies. Much depends on factors such as the philosophy and rationale for the standards, the process of standard setting, nomenclature and applicability, and whether economic considerations and technical feasibility are taken into account.

In the United States, threshold limit values (TLVs) for chemical substances and physical agents are set and reviewed annually by the American Conference of Governmental Industrial Hygienists (ACGIH). These TLVs are one of the best known and widely used of the occupational exposure limits (OELs). They are derived using information from industrial experience, as well as studies in both animal and human populations. These standards are adopted by

many countries, especially those without their own national occupational exposure standard setting mechanism.

The US also has recommended exposure limits (RELs) produced by NIOSH, and permissible exposure limits (PELs) from the Occupational Health and Safety Administration (OSHA). The United Kingdom has Workplace Exposure Limits (WELs), and in Germany there are two groups of OELs: (1) technical guidance concentrations (TRKs), and (2) maximum concentration for a chemical substance in the workplace (MAK).

Permissible levels have their limitations. For example, a 'safe' level of exposure can be difficult to determine for agents such as allergens and carcinogens. As such every effort must be made to keep exposure levels as low as reasonably practicable and the permissible level is then a level above which exposure must not occur. This level may be mandated by legislation. Concerns regarding health risks have arisen from substances assumed previously to be safe, for example, glycol ethers in the electronic industry associated with the risk of spontaneous abortions have led to further investigations into whether retention or lowering of the current occupational exposure levels is warranted. Standards that are set for an 8-hour working day would not be applicable for a 12-hour work shift. Furthermore, exposure to several hazards simultaneously does occur. In such situations, there can be possible synergistic or additive effects. This would then require more stringent control of each individual hazard.

The methods for environmental monitoring require choice of the correct collecting devices, sampling strategy, and analysis of the collected samples in accredited laboratories. Variations in age, gender, pre-existing disease, genetic makeup, and social habits, for example, smoking, influence individual susceptibility and have to be considered in applying the findings from exposure assessment to the exposed population. Despite these limitations, sensible use of environmental standards can often result in practical control of many common workplace hazards so that the majority of workers are protected.

Biological monitoring

Biological monitoring refers to the measurement and assessment of workplace agents or their metabolites either in tissues, secretions, excreta, expired air, or any combinations of these to evaluate exposure and health risk compared to an appropriate measure. The specific chemical or its breakdown product can be measured to detect the total body burden of the substance. The method of measurement of these substances must be validated and there should be a means to interpret the results obtained in terms of the extent of exposure, and risk to health.

Biological monitoring and environmental monitoring complement each other in the assessment of health risk in the exposed worker. One major feature of biological, as compared to environmental, monitoring is that for a particular individual, it takes into account exposure from all routes of absorption. For example, for workplace exposure to organic solvents, skin absorption may be a significant route of entry of the solvent into the body, and ambient environmental air monitoring might be less useful as an indicator of exposure than biological monitoring. Furthermore, environmental monitoring at the workplace would not account for non-occupational or extra-occupational exposures. A person exposed to organic solvents at work may have additional exposure at home as a result of hobbies or other non-occupational activity.

While the term 'biological monitoring' has previously been used to also include clinical procedures (e.g. periodic X-rays, blood tests, symptom enquiry, etc.) for monitoring the health status of exposed workers, it is preferable to make a clear distinction between the terms 'biological monitoring' (used for assessing exposure), and 'biological effects monitoring' and 'health surveillance' (used for detecting effects).

Biological monitoring standards

A set of values has been developed by the ACGIH, for interpreting results of biological monitoring (as well as biological effects monitoring). The Biological Exposure Index (BEI) is described as representing the 'levels of determinants that are most likely to be observed in specimens collected from healthy workers who have been exposed to chemicals to the same extent as workers with inhalation exposure at the TLV' (ACGIH 2012). Exceptions would be made for chemicals for which TLVs are based on non-systemic effects, for example, irritation; and for chemicals with significant routes of entry via additional routes of entry (usually percutaneous absorption).

The ACGIH cautions that BEIs are not able to clearly distinguish hazardous from non-hazardous exposures. Biological variation in individuals may sometimes result in measurements in individuals to exceed recommended BEI levels without an increased health risk (ACGIH 2012). It further states that BEIs are not intended for use as a measure of adverse effect or diagnosis of occupational disease. However, if measurements of the individual or group of workers persistently exceed the BEIs, the cause of the excessive values should be investigated, and measures should be taken to reduce the exposure.

The UK HSE has similar values for a smaller number of compounds. These are termed biological monitoring guidance values (BMGV).

Assessing health effects

Biological effect monitoring

This refers to the measurement and assessment of early biological effects, of which the relationship to health impairment has not yet been established, in exposed workers to evaluate exposure and/or other health risk compared to an appropriate reference. Some examples include detection of alterations in enzyme levels (e.g. cholinesterase for workers exposed to organophosphorus or carbamate pesticides), or other biochemical changes such as delta-aminolaevulinic acid in urine of workers exposed to inorganic lead, or beta-2 microglobulin in the urine of cadmium exposed workers. These changes do not necessarily lead to any direct overt pathological damage in an individual, but may reflect effects that are often reversible on removal of the worker from further exposure.

Recent technological advances in molecular biology have resulted in the development of newer molecular biomarkers of exposure, response, and genetic susceptibility. These include measurements for structural gene damage, gene variation, and gene products in cells and body fluids, for example, oncogenes and tumour suppressor genes, DNA adducts, gene products and genetic polymorphisms, and metabolic phenotypes in environmentally exposed populations (Koh et al. 1999). The availability of genetic tests to identify susceptible workers raises issues of ethics, individual

privacy, right to work, and the relevance of such tests. Given the limitations of individual molecular biomarkers in assessing health risk, and the multifactorial nature of environmental disease, it is likely that a combined approach which examines several of these biomarkers simultaneously will increase our understanding of the complex issue of disease mechanisms and further refine the process of occupational risk assessment.

Health surveillance

This refers to the detection of health effects through the periodic physiological or clinical examination of exposed workers with the objective of protecting and preventing occupationally related diseases. Examples are audiometry for noise exposed workers, and clinical examination for skin lesions in workers exposed to polycyclic aromatic hydrocarbon compounds in tar, pitch, and bitumen. The use and limitations of periodic medical examinations are discussed further in the section on secondary prevention.

Managing the risk of work and promoting health at work

Prevention of occupational disease can take place at various levels, such as at the national level, at the level of the workplace itself, or measures directed at the individual worker.

Primary prevention aims at reducing the occurrence of disease by eliminating the causal factors contributing to disease or reducing workplace exposure to safe levels. Examples are banning the use of asbestos to prevent asbestosis, mesothelioma, and lung cancer, and reduction of noise at its source to levels that do not cause noise-induced deafness. Primary prevention with regard to chemicals requires either: (1) elimination of toxic materials and their replacement by less hazardous substitutes or (2) use of safe systems of work, and controls such as complete enclosure or local exhaust ventilation at the source of aerosol generation.

Secondary prevention aims to detect over-exposure, or early reversible effects of disease in order to take corrective action. For example, regular monitoring of blood lead levels among exposed workers could indicate a potential for lead poisoning, or regular audiograms among noise-exposed workers may show temporary threshold shift (TTS). Removal of workers with TTS from further noise exposure, and subsequent containment of the source of the noise can allow recovery of hearing, and a return to regular work duties. Successful secondary prevention depends on the ability to identify work-related illness early and effectively through screening workers at high risk for occupational disease.

Tertiary prevention aims to minimize the consequences in people who already have established disease. This activity is primarily a curative and rehabilitative function and depends on availability of appropriate treatment. However, even for acute poisonings, there are very few specific effective antidotes available. Hence, the focus should be on primary or secondary prevention.

Prevention at all three levels requires information on the nature and extent of exposure, and knowledge of the potential effects of these exposures.

Primary prevention

Control of new hazards

Laboratory toxicology studies using animal models and/or cell lines are used to predict potential effects of hazardous materials on

humans. The findings from such studies determine whether substances or groups of substances are marketed for use in industry and/or in the community. The European Union's REACH (Registration, Evaluation, Authorisation, and Restriction of Chemicals) regulations which came into force in June 2007 placed an obligation on manufacturers, importers, and users of chemicals in Europe to register and provide information on hazardous chemicals and risk reduction measures (European Chemicals Agency 2012). The regulations also promote the use of methods of risk assessment that reduce the need for animal testing

Control of known hazards

Several countries have legislation to ban the use of substances known to be harmful to human health. The UN has compiled a consolidated list of products whose consumption and sale have been banned, withdrawn, severely restricted, or not approved by governments. This publication constitutes a tool that helps governments keep up to date with regulatory decisions taken by other governments and assists them in considering the scope for eventual regulatory action. The United Nations Environment Programme (UNEP) in 1989 has evolved a procedural mechanism of prior informed consent (PIC) to inform government of banned agents such that these governments could take appropriate action for their control. By such means, the UN system attempts to prevent importing countries from unknowingly using substances banned in other countries for health reasons. At the national level, there may be rules that regulate the import, storage, sale, and transport of legislated substances through a licensing system, for example, for pesticides. Some substances may be subjected to import controls.

Control measures within the workplace

Within the workplace, a hierarchy of control measures is often invoked for reducing occupational hazards. This consists of considering the following steps listed according to order of priority:

1. Hazard elimination or substitution.
2. Engineering controls.
3. Redesign of the workstation or work process.
4. Administrative controls and worker education.
5. Use of personal protective equipment.

Elimination of the hazard or substitution with a safer alternative

This option eliminates the health risk completely, and has been used for substances that are carcinogenic—such as asbestos and benzene, or those that can cause serious health effects such as heavy metals. For example, it is possible to produce new soldering materials that contain little or no cadmium at all, and the HSE in the United Kingdom has produced legislation for this elimination (Mason et al. 1999).

Substitution of the hazard with a less toxic alternative is another option. In the case of processes which use solvents, such as degreasing operations, a less toxic solvent such as 1,1,1 trichloroethane can be used, instead of the comparatively more toxic trichloroethylene or tetrachloroethylene.

Selection of a less hazardous process or equipment also represents a meaningful control strategy. For example, substitution of a continuous process by an intermittent process almost invariably results in a decrease in exposure. Instead of replacing an entire work process to reduce hazards, equipment substitution may achieve the

desired reduction in exposure. An example is use of a degreaser with a hoist instead of dipping components into solvents by hand.

Engineering controls

Automation, enclosure, or segregation of a work process, and the use of dampeners or mufflers to reduce vibration or noise have been successful engineering control measures used.

Improved ventilation is also an effective and widely used control measure. Control of hazards by ventilation can be through local exhaust ventilation or general ventilation. The approach for implementing ventilation controls is firstly to conduct an engineering study to evaluate sources of exposure; secondly, to develop an engineering design; thirdly, to install a system based on the design; and lastly, to evaluate the completed system to ensure that the air contaminant has been effectively controlled.

Isolation is defined as the interposing of a barrier between a hazard and workers who might be injured or made ill by the hazard. Isolation may refer to storage of materials, such as flammable liquids, enclosure or removal of equipment to another area (such as noisy generators), or isolation of processes or of the workers themselves (e.g. by enclosing a sawmill worker in a soundproof ventilated booth to protect them from noise and wood dust). The petroleum industry, for example, uses automated remote processing in plants based on centralized computer control of process equipment. Workers are thus largely isolated from hazards except in maintenance operations and during process upsets.

Suppressing the substance by 'wetting' of dusty operations is another example of effective engineering control. Alteration of work practices can help to reduce exposure to hazards. An example is vacuuming cotton lint off spinning machines rather than blowing it off with compressed air, a practice which creates airborne dust particles.

Redesign of the workstation or work process

Workstation redesign to reduce unnecessary and repetitive bending, or poor postures can minimize ergonomic hazards. Among computer operators, use of adjustable equipment, positioning of the workstation to reduce glare, and provision of appropriate work rest periods can prevent the occurrence of visual and musculoskeletal complaints.

Administrative controls and worker education

Administrative controls may be a viable alternative or an additional measure to reduce worker exposure to occupational hazards. This could take the form of job enlargement or job rotation, restriction of hours of work at a hazardous operation, or temporary job reassignment.

With administrative controls, the level of exposure to the hazard is not diminished; instead, the duration of exposure is reduced. For example, mandatory rest periods and shorter work hours for outdoor workers during extremely hot weather (as in desert environments) have helped to reduce the likelihood of heat stress. Another example is the reduction of overall noise exposure through rotation of tasks. Given the typical demands of production and the potential for misuse, administrative methods of controls should never be a first-line choice for control of hazards.

Training of workers to recognize work hazards, to work safely, and to know what to do in the event of an emergency is another important aspect of prevention. There may be considerable variability in exposure even amongst a group of workers supposedly performing the same work tasks (Symanski et al. 2001). This variation

can be explained by differences in hazard awareness, attitude, and practice of safe working techniques in different workers.

Programmes for encouraging personal hygiene constitute another approach to reducing exposure. The provision and use of showers and a change to clean clothes at the end of the working day is a practical personal hygiene measure. Indeed, US OSHA standards, such as the occupational lead standard, require management to provide such facilities. A subtle but potentially important route of exposure is ingestion of toxic agents through eating or smoking, at the workplace. To prevent such exposure, separate facilities for consumption of food away from production lines should be provided.

Use of personal protective equipment

It is axiomatic that use of personal protective devices to prevent occupational ill health should be considered as a last resort after all other methods for minimizing exposure to workplace hazards have been tried. PPE can never be as efficient a means of protection as engineering or process controls. Nevertheless, the use of PPE is often widely practised, perhaps because it is seen as a relatively low-cost measure that puts much of the onus on the worker for compliance with use. PPE can be useful for short-term (as for emergency rescue work) or infrequent exposure to occupational hazards. Respirators, gloves, protective clothing, ear plugs, and muffs are all common forms of PPE in use throughout industry. They can play an important role, provided that carefully designed PPE programmes are in place and that the devices are frequently and regularly checked.

Protective devices should be properly selected to be effective against specific hazards, for example, the choice of an appropriate glove for use with a particular solvent. Workers have to be trained to use the equipment correctly and to ensure that it is working effectively, such as respirator fit testing in the use of respirators. Worker compliance in the use of these devices has to be high, or its protective effects may be less than desired. Compliance can be an issue, because of discomfort, especially for workers in hot and humid climates. Protective devices also have to be properly maintained and replaced when necessary.

Secondary prevention

Secondary prevention aims to detect situations of early effects of disease before they manifest as clinical symptoms and signs. Upon early detection, corrective action can be taken, such as removal of the worker from further exposure. In most instances, early effects of disease can be reversed if corrective action is promptly taken.

Pre-employment examinations

The often stated aim of these assessments is to detect any mismatch between the job applicant's health and the intended job. A decision can then be made by management as to whether or not the person should be hired. Cost considerations and concerns about inability to carry out the full range of work tasks and possible harm to third parties are often given as reasons for rejection of an applicant. In practice, the detection rate for relevant clinical abnormalities is low (2 per cent in prospective healthcare workers in the United Kingdom) (Whitaker and Aw 1995), such that the cost-effectiveness of the process is questionable. There is an element of selection bias since individuals who are in poor health with existing clinical abnormalities are unlikely to be seeking employment. Pre-employment examinations probably constitute one of

the most frequent procedures performed by occupational health departments especially in developing countries. In many developed countries there are laws prohibiting discrimination on the basis of health status. Individuals are hired primarily on the basis of their credentials and ability, and subsequent adjustments to the job tasks or work environment can then be made if indicated for health reasons.

Where they are performed, the pre-employment examination or the pre-placement assessment can be used as an occasion to obtain baseline data on health status or fitness, to inform and educate the new worker about potential hazards in their work and the preventive measures that can be taken to safeguard their health. Immunization against diseases that may possibly be contracted on the job, and for which an effective vaccine is available, should also be given. An example is the immunization of healthcare personnel exposed to the hepatitis B virus. Some genetic disorders which can be identified at the pre-employment stage may enable suitable advice to be given in regards to special care in handling chemicals at work, for example, people with glucose-6-phosphate dehydrogenase deficiency are at risk of haemolytic anaemia on exposure to naphthalene and fava beans. People with serum total alpha-1-antitrypsin deficiency may be susceptible to smoke, fumes, and other respiratory irritants (Koh and Jeyaratnam 1998).

Periodic medical examinations

The aim of statutory medical examinations is to prevent special groups of 'at-risk' workers from developing serious occupational diseases. Regular health examinations, which are specific for the type of hazard the worker is exposed to, are conducted. Workers found to have signs of overexposure to the hazard or with early signs of disease can be removed from further exposure. They can be given alternative work until they are fit to return to their former jobs. Furthermore, if signs of overexposure are detected, additional control measures can be taken to reduce the exposure at source, and prevent other workers from being similarly affected.

Special groups of workers are required to undergo periodic medical examinations for protecting the health of the public, for example, professional drivers and food handlers.

In many countries, employment laws require specified categories of employees to undergo statutory periodic medical examinations, for example, for workers exposed to known hazards such as noise, radiation, asbestos, silica, and heavy metals. In principle, this approach to prevention sounds reasonable, that is, to detect health effects from occupational exposure early in order to take preventive action. In practice the usefulness of such regular procedures is questionable. For example, examining radiation workers for the early effects of radiation exposure or performing annual chest X-rays on workers exposed to fibrogenic or carcinogenic dusts (asbestos, silica) has little beneficial effect on prevention. This is because radiological changes in the chest as a result of exposure to these dusts occur after a long latent period, and by the time the changes are detected, irreversible damage has already occurred. The prospects for effective treatment are often limited. The prevention of disease in other exposed workers would need to involve control measures instituted at a much earlier stage before X-ray changes appear.

For the countries that require statutory periodic medical examinations, these are often only to be carried out by qualified health personnel, with additional postgraduate training in occupational health. There is usually stipulation for the results of the

examinations to be kept for a specified period of time, and copies of examination or investigation findings need to be sent to the relevant government agency.

Post-illness or injury evaluation

An evaluation of the health status of the employee returning to work after a prolonged absence from work due to illness or injury can help ensure that the worker has sufficiently recovered, and is fit to return to work duties. Several issues to consider are:

1. Can the worker perform his/her duty without compromising his/her health and safety or that of fellow workers and others?
2. Is the worker capable of performing the work efficiently despite any residual impairment of function that has resulted from the illness?
3. Could the worker benefit from some adjustment to the work process, provision of additional or modified equipment, or alteration to the system of work?
4. Should he/she return to previous full-time unrestricted duty, or should alternative work be considered?

Notification of occupational diseases

Most countries require the statutory notification of occupational diseases to the government. This allows investigation, confirmation, and follow-up of cases by the authorities, and an analysis of trends over time. A single notified case may indicate poor control of work hazards that can pose a risk to other workers in the same work environment. Thus, it fits in with the concept of secondary prevention in that the sentinel 'notified' case may enable exposure to be further controlled before overt disease occurs in other exposed workers. The responsibility for notification has involved doctors, employers, or employee representatives, and varies between countries. Many countries produce a list of notifiable occupational diseases. This can be different from a list of prescribed diseases for which individuals may obtain financial compensation.

Notification serves as an additional means of control of occupational diseases. It should initiate a chain of events, starting from investigation and confirmation of the index case, and active case finding of other affected people. Recommendations for specific preventive measures at the workplace are then prescribed. The authorities would follow up by ensuring that the recommendations have been implemented. If necessary, further evaluation of the effectiveness of the preventive measures can be made.

Tertiary prevention

Tertiary prevention involves mainly early treatment and rehabilitation. For occupational ill health, affected workers should be removed from further exposure, and the appropriate medical treatment given as necessary. Examples of appropriate treatment include the rendering of first aid promptly after an injury, chelation for severe cases of heavy metal poisoning, atropine and aldoximes for organophosphate poisoning, antidotes for cyanide poisoning, use of calcium gluconate for hydrofluoric acid burns, and hyperbaric treatment for cases of compressed air illness. Treatment would also include prompt provision of clinical supportive measures.

Planning for emergency response

Occupational health personnel can assist in developing plans to cope with disasters in the workplace that may also affect the

surrounding community. In addition to first aid and acute health-care provisions, other aspects such as fire and emergency response services are essential. Planning and practice drills should be done jointly with the relevant local community agencies.

Rehabilitation

Rehabilitation of workers is another important aspect of occupational health practice. Management, co-workers, occupational health professionals, and the injured worker have to work together to ensure that suitable alternative duties are provided, and that any work restrictions or physical limitations are understood. There should be clear short- and long-term goals in rehabilitation, and alternative duties should be meaningful and contribute to production (Australasian College of Occupational Medicine and Australian College of Rehabilitation Medicine 1987). Sometimes, the use of external rehabilitation resources may be needed.

Workers' compensation

In many countries, workers who are injured at work or fall ill from hazardous work exposures are eligible for compensation. Workers' compensation is designed to provide income support, medical payments, and rehabilitation payments to workers injured on the job, as well as to provide benefits to the family and dependants of fatally injured workers. Most industrialized countries have workers' compensation programmes. In some countries, certain categories of workers, for example, domestic helpers are excluded. In many countries, employers have social insurance to give protection to employment injury victims. The principle of social insurance is that of sharing of risks and pooling financial resources. A social insurance scheme establishes a public channel through a government department or government supervised body, which oversees procedures of screening, determination of award and payment of benefits.

Benefits are payable for temporary incapacity or permanent incapacity, and include survivors' benefits for those killed at work. Guidelines for assessment of disability are available in most countries. The final assessments for disability are made when the worker's medical condition has stabilized, and not likely to improve or deteriorate further. Besides workers' compensation and social insurance schemes, injured workers can sue their employer for negligence through common law. This can be a lengthy process in some countries (although not in the United Kingdom), acceptance of benefits from a state or federal workers' compensation scheme requires waiver of the right to sue the employer.

Health promotion at the workplace

The WHO defines health promotion in its broadest sense as 'the process of enabling people to increase control over, and to improve their health'. Health promotion is an integral part of a comprehensive occupational healthcare system (WHO 1988).

It is a process of activating communities, policymakers, professionals, and the public for health supportive policies, systems, and ways of living. It is manifested by promoting healthy lifestyles and community action for health, and by creating conditions that make it possible to live a healthy life. The workplace is a suitable venue to develop and provide health promotion for individuals and for groups of workers. These activities include cessation of smoking, providing dietary advice, encouraging exercise and physical activity, promoting healthy lifestyles, reducing cardiovascular and other risks, and emphasizing compliance with health and safety measures at the workplace.

Table 7.4.1 Comparison of occupational health and environmental health

Occupational health	Environmental health
Hazards in workplace environment	Hazards in community environment
Hazards largely in air	Hazards in air, soil, water, and food
Hazards are physical, chemical, biological, and psychosocial	Hazards are physical, chemical, biological, and psychosocial
Route of exposure: inhalation and dermal	Route of exposure: ingestion, inhalation, and dermal
Exposure period: 8 hours/day for working life	Exposure period: 24 hours a day, lifelong
Exposed population: adults, usually healthy	Exposed population: children, adults, elderly (includes the sick and infirm)

From occupational health to environmental health

Occupational health practice today has evolved to include consideration of environmental health issues. There are several reasons for the increasing convergence of the two disciplines. Firstly, many sources of pollution originate from the workplace. Secondly, especially in regards to work and health, there can be an overlap between the work environment, the home environment, and the general environment, for example, in agriculture and in cottage and small-scale industries. In these examples, there is often no clear demarcation between the workplace and the home. Thirdly, there are several areas of common ground between occupational and environmental health. Table 7.4.1 compares the factors in the work environment that influence the health of the working population (occupational health) with that of the general environment affecting the health of the community (environmental health).

Occupational health practitioners have the necessary skills in clinical medicine, toxicology, hygiene, epidemiology, and preventive health to contribute to the management of environmental health concerns, especially those resulting from workplace activity. The success of both occupational health and environmental health in regards to investigations, interventions, and implementation of prevention relies heavily on good communication between the professionals and the stakeholders.

Conclusion

Workers suffer a broad range of injuries and illnesses caused by hazards encountered in the workplace. In the practice of occupational health, prevention of work-related and occupational disease is a key objective. It also includes efforts for preventing occupational injury. Prevention can be at the primary, secondary, or tertiary level. Reducing exposure to occupational hazards in the workplace is the mainstay for reducing the burden of occupational ill health. The workplace is also an ideal setting for health promotion activities, although the benefits from health promotion will only be realized if occupational hazards are first controlled.

The importance of occupational health lies in its emphasis on prevention, and in this respect it shares common objectives and strategies with public health. Occupational health focuses mainly on a specific group in the community—those in employment. Public health covers the health interests of the whole community. There is much merit and scope for closer links between occupational health, environmental health, and public health.

Toxicology and risk assessment in the analysis and management of environmental risk

David Koh, Tar-Ching Aw, and
Bernard D. Goldstein

Introduction to toxicology and risk assessment in the analysis and management of environmental risk

Toxicology is the study of the science of poisons. In theory, any substance can cause harm to health. To paraphrase the immortal words of the physician alchemist Paracelsus, 'It is only the dose that distinguishes a poison from a remedy'. To that we can also add that the route of entry into the body can also determine the extent of injury or ill health. In practice, most poisons are either chemicals or biological materials that cause severe effects in relatively small doses. Poisonous substances that contaminate the environment can lead to an increased risk of ill health in exposed populations. The level of risk is a function of the extent of exposure and the susceptibility of those exposed. An understanding of toxicology is essential in determining and managing environmental risk.

The goal of this chapter is to synthesize toxicology and risk assessment as a basis for evaluating human health risks posed by chemical, biological, and physical agents in the environment. Disciplines other than toxicology, such as epidemiology and exposure assessment, are also required to better understand risk, and for many specific agents will provide the major basis for the information underlying risk assessment and risk management.

Environmental risk analysis is a broad field, encompassing risks to ecosystems and materials as well as to human health. Only human health risks will be considered in this chapter. However, the link between human and environment health is obvious. Risk to ecosystems can often serve as a warning about human health risk. As an example, the concern about the impact of acid deposition on trees and lakes preceded by about two decades the recognition that relatively low atmospheric concentrations of fine particulates as part of acid deposition are a human health risk. Another related example is the impact of global climate change on human health (see Box 7.5.1).

Toxicology has two important roles in environmental risk management:

1. The ascertainment of cause and effect relationships linking chemical and physical agents to adverse effects in humans or the general environment.
2. The development of techniques capable of preventing these problems.

Toxicologists usually approach questions of disease causation by starting with the chemical or physical agent and studying its effects in laboratory animals or in test-tube systems. An exciting aspect of modern toxicology is the development of tools, primarily through molecular biology and advanced computational techniques, capable of probing the extent to which a given disease in an individual is caused by a chemical or other environmental factor. This reversal of approach, in which we start with disease and move towards determining the cause, is enabled by the increasing ability of epidemiology to link subtle biological markers indicative of early effects to biological markers indicative of exposure.

Toxicology is also an important discipline in the primary and secondary prevention of human health effects. Understanding the mechanisms by which chemical agents cause biological effects can result in toxicological tests useful to prevent the development of harmful chemicals, or the early detection of potential adverse effects.

General concepts of toxicology relevant to risk assessment

Knowledge about poisons extends back to the beginning of history as humans became aware of the toxicity of natural food components. The bible contains injunctions concerning poisons, including how to avoid them. Greek and Roman history gives evidence of the use of poisons as an instrument of statecraft, an approach that was extended in the Middle Ages with such notable practitioners

Box 7.5.1 Case study: global climate change and human health

Unprecedented social and demographic changes and evolving patterns of economic activity have resulted in large-scale and systemic environmental impacts. One such impact is the rapid increase of greenhouse gas emissions and the resulting global climate change (McMichael 2013).

Human health can be impacted by direct biological consequences of extreme weather events, for example heatwaves, through temperature-enhanced levels of urban air pollutants; and via increased health risks from changes in biophysically and ecologically based processes and systems, for example, food yields, water flows, infectious-disease vectors, and intermediate-host ecology for zoonotic diseases. There are also more diffuse and indirect effects, such as mental health problems in failing farm communities, displaced groups, disadvantaged indigenous and minority ethnic groups, and consequences of tension and conflict owing to climate change-related declines in basic resources (water, food, timber, living space).

as the Borgias. Toxicologists credited Paracelsus with the first law of toxicology, that the dose makes the poison. There are two other major maxims that underlie modern toxicology: that chemicals have specific biological effects, a maxim that has been credited to Ambrose Pare (Goldstein and Gallo 2001); and that humans are members of the animal kingdom.

The 'laws' of toxicology

The following subsections discuss 'laws' and general concepts of toxicology pertinent to understanding how a chemical or physical agent acts in a biological system. The focus will be on the biological response, rather than on the intrinsic properties of the agent. The three 'laws' of toxicology are:

1. The dose makes the poison.
2. Chemicals have specific effects.
3. Humans are animals.

The first law: the dose makes the poison

Central to toxicology is the exploration the relation between dose and response. As a generalization, there are two main types of dose-response curves (Fig. 7.5.1). One is an S-shaped curve that is characterized by having at lowest doses no observed effect and, as the dose increases, the gradual development of an increasing response. This is followed by a linear phase of increase in response in relation to dose and, eventually, a dose level at which no further increase in response is observed. Of particular pertinence to environmental toxicology is that this curve presumes that there is a threshold level—below which no harm whatsoever is to be expected. There is ample scientific basis for the existence of thresholds for specific effects. For example, if one drop of undiluted sulphuric acid is splashed onto the skin it is capable of producing a severe burn. Yet one drop of pure sulphuric acid in a bathtub of water is sufficiently dilute to be without effect. Thresholds for an adverse effect will differ among individuals based upon a variety of circumstances, some of which are genetically determined and others may represent

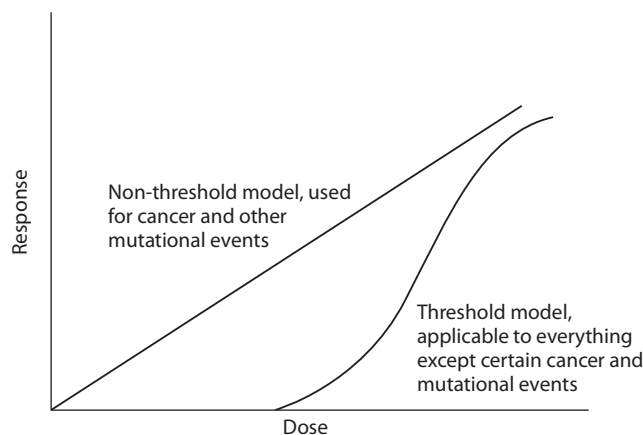

Fig. 7.5.1 Dose-response curve.

stages of life or specific circumstances. In the example of sulphuric acid on the skin, there are genetically determined differences in susceptibility related to the protective presence of skin hair; babies will be more susceptible than adults; and skin that is already damaged will be at particular risk. This S-shaped dose-response curve is assumed to fit all toxic effects except those that are produced by direct reaction with genetic material.

The second general type of dose-response curve covers end points caused by persistent changes in the genes. This occurs in cancer, in which a somatic mutation occurring in a single cell results in a clone of cancer cell progeny. Another example is inherited mutations of the genetic components of cells involved in reproduction. It is believed that a single change in DNA can alter the genetic code in such a way to lead to a mutated cell. It therefore follows that any single molecule of a carcinogenic chemical or packet of physical energy such as ionizing radiation, that can alter DNA is theoretically capable of causing a persistent mutation. The presumption that every single molecule or ionizing ray has the possibility of changing a normal cell to a cancerous cell implies that there is no absolutely safe dose. The resultant dose-response curve starts at a single molecule, that is, it has no threshold below which the risk is zero. As a further simplification, the shape of the curve can be linearly related to dose in that the risk of two molecules of a DNA-altering chemical causing a mutation is conceivably twice that of one molecule, and so on, until a dose level results in dead cells.

Features of both the S-shaped and linear dose-response curves occur in the body's response to allergens. It is likely that a relatively large dose of an allergen is required to sensitize an individual (i.e. with a threshold dose for sensitization that may vary with the agent and the individual). However, once sensitized, the affected person may react to molecules of the causative agent with no apparent threshold for elicitation of a reaction.

There are also a few chemicals that have a U-shaped dose-response curve. This is where high levels of exposure cause harm and insufficient amounts lead to deficiency which results in ill health. Examples are fat-soluble vitamins and essential trace minerals. Excess vitamin D intake causes hypervitaminosis D, and vitamin D deficiency leads to rickets and osteomalacia. There is therefore an ideal range for vitamin D levels which results neither in deficiency nor poisoning.

The second law: specificity of effects

That chemical and physical agents have specific effects is in essence no different than recognizing that possession of a gun does not make one a murder suspect if the victim has been stabbed to death. The law of specificity is well understood by the general public in terms of drugs: aspirin will help with your headache but is useless for constipation, while laxatives have the opposite effect. However, various surveys suggest that the selectivity of effects of environmental chemicals is not well understood by the lay public; many believing that a chemical that can cause cancer in a particular organ can cause cancer and other diseases anywhere in the body. Some chemicals may cause malignancy in more than one body site (e.g. asbestos as a cause of lung cancer, peritoneal mesothelioma, and laryngeal cancer), but in general, chemical and physical agents are highly specific in their effects.

The specificity of effects is due both to chemistry and to biology. Understanding the relationship between chemical structure and biological effect has been central to both pharmacology and toxicology. Structure–activity relationships (SARs) are often used as a means to design a chemical with a specific effect that might be useful as a therapeutic agent. SARs are also used to predict whether a new chemical being readied for manufacture might be of potential harm. While SARs are a useful tool which is being improved through modern computational approaches, their predictive values remain too limited to be used without recourse to additional testing of a potentially toxic agent. For example, only one simple methyl group separates toluene from benzene, with only the latter known to cause bone marrow damage and leukaemia; ethanol from methanol, the latter causing metabolic acidosis, renal failure, and blindness; and *n*-hexane from either *n*-heptane or *n*-pentane, with only *n*-hexane being responsible for peripheral nerve damage. These examples of specificity reflect both the formation of toxic metabolites, such as active species derived from the metabolism of benzene, and the interaction of a chemical or its metabolite within specific biological niches, such as the diketone metabolite (2,5-hexanedione) of *n*-hexane within neuronal axons.

Specificity of effects is also conferred by cellular processes that lead certain cells to be more susceptible to environmental agents. For example, red blood cells have the iron-containing protein haemoglobin that is responsible for the transport of oxygen. Toxicity through alteration of efficient oxygen delivery occurs through certain specific mechanisms. One is through the oxidation of the reduced ferrous form to the ferric form of iron, known as methaemoglobin, which can no longer carry oxygen. This occurs with a limited number of agents (e.g. nitrates and phenols) that once within the red blood cell are capable of oxidizing intracellular iron. Another specific mechanism of interference is exemplified by carbon monoxide. This otherwise relatively inert gas has a physical chemistry that sufficiently resembles oxygen so that it is able to tightly combine with the oxygen combining site of haemoglobin, thereby displacing oxygen. There are many other examples in which in essence a normal body process is disrupted by an exogenous chemical through a specific chemical alteration, such as oxidation or covalent addition, or by fitting into a niche designed through evolution to accommodate a necessary internal chemical which it superficially resembles.

The third law: humans are animals

The conceptual foundation for extrapolating from animals to humans is a central facet of modern toxicology. The basic principles

of cell function are common to all of biology. All cells must obtain energy, build structure, and release waste. Cell function in complex organisms such as humans is highly specialized, but there is still a great deal of similarity in cellular and organ function among mammals facilitating extrapolation of effects from one species to another. In general, the specificity of toxic effects is relatively similar across mammals, for example, a kidney poison in one species is likely to be a kidney poison in another, although there are certainly exceptions. Arsenic is an example of a human carcinogen where the animal evidence for carcinogenicity is lacking. However, dose–response considerations often vary substantially, reflecting differences in absorption, distribution, metabolism, excretion, function, and target organ susceptibility between species. Understanding the factors responsible for inter-species differences greatly facilitates extrapolation from animals to humans. Once elucidated, the role of different absorption rates, metabolism, or other factors can be taken into account, often through a mathematical approximation that has come to be called physiologically based pharmacokinetics (or toxicokinetics). One of the greatest threats to the public health value of toxicological sciences comes from animal rights activists who in their arguments against animal research intentionally ignore the major positive impact of animal toxicology on the well-being and lifespan of animals, including pet dogs and cats.

Pathways of exogenous chemicals within the body

The four major processes governing the impact of an exogenous chemical within the human body are absorption, distribution, metabolism, and excretion. All can vary greatly among different individuals, and within the same individual depending upon, for example, stage of life and state of health. These variations are among the major reasons for differences among humans in susceptibility to risks from exposure to chemical and physical agents. The increased understanding of how the human genotype and phenotype affects absorption, distribution, metabolism, and excretion of external agents, including foods, is providing insight into answers to the oldest human question about disease: ‘Why is this happening to me?’ (Omenn 2000).

Absorption

Absorption of a chemical into the body occurs through ingestion, inhalation, and across the skin. Depending upon the specific chemical, the route of exposure can have major implications on the extent of absorption and the resultant toxicity. For example, almost 100 per cent of inhaled lead-containing fine particles are absorbed into the body as compared to a much smaller percentage of ingested lead. Internal factors also can affect absorption, particularly from the gastrointestinal tract. In the case of lead absorption, iron and calcium deficiencies both produce an increase in absorption of ingested lead. The matrix of the exposure agent also may have an effect. For example, the rate at which benzene in gasoline is absorbed through the skin will likely be increased by oxygenated components of the gasoline mixture; and the absorption of dioxins from contaminated soil can vary enormously (Umbreit et al. 1986). The American Conference of Governmental Industrial Hygienists (2013) provides a ‘skin’ notation for chemicals that can be absorbed through the skin to cause systemic effects following exposure.

Often, a single route of absorption is dominant. But, in many instances, more than one route is important. For example, exposure to chlorinated disinfection products in drinking water systems, or gasoline contamination of well water through a leaky underground storage tank, is usually thought of solely in terms of the ingestion of water. However, during showering there is likely to be both inhalation and transdermal absorption, and if groundwater is contaminated there can be off-gassing from soil into the home. Epidemiological studies of the potential adverse consequences of water contamination need to take all of these exposure routes into account (Arbuckle et al. 2002).

Other less common routes of absorption can be through the intravenous, intramuscular, intraperitoneal, or sublingual route, or via suppositories. These occur mainly in animal experiments or in human drug delivery. A novel route of absorption is the translocation of nanoparticles deposited in the nasal area via the olfactory nerves directly into the brain (Oberdörster et al. 2004).

Distribution

Once inside the body, distribution of the chemical occurs through different pathways. In part, this depends upon the route of absorption. Most compounds absorbed in the gastrointestinal tract go directly to the liver and may go no further. The liver has a strong capacity to detoxify many absorbed chemicals. This first-pass effect occurs when a toxin or drug is absorbed by the digestive system and enters the hepatic portal system into the liver before it reaches the rest of the body. Enzymes of the gastrointestinal bacteria, lumen, gut wall, and liver contribute to the first-pass effect, which may greatly reduce the bioavailability of the toxin or drug in the systemic circulation. On the other hand, inhaled agents first go to the lung or other parts of the respiratory tract and then to the general circulation without being impacted by the first-pass effect.

Distribution also depends upon the chemical and physical properties of the agents. Small inhaled particles tend to be distributed deep within the respiratory tract while larger particles get filtered out in the nose or are trapped and cleared by the bronchiolar mucociliary escalator. Particles sized less than 2.5 microns are most likely to penetrate to the lower respiratory tract and alveoli. Chemicals that are poorly soluble in water, for example, oils, usually distribute within fatty tissues. Only certain types of compounds, for example, alcohols are able to cross the blood–brain barrier. Organ-specific factors are also important, for example, a specific pump located in the thyroid gland facilitates uptake of iodine and makes the thyroid particularly vulnerable to the adverse impact of radioactive iodine.

Metabolism

Metabolism in the narrowest sense of the term refers to alteration of chemicals by the body. The major metabolic function of the body is to alter food into energy or structural materials. Metabolism of xenobiotics (chemical compounds that are foreign to a living organism) is often protective, converting unwanted absorbed materials into chemical forms that are readily excretable. Thus, a fat-soluble agent can often be converted into water-soluble agents capable of being excreted in the urine. However, for certain classes of chemicals, metabolism results in conversion of relatively inactive compounds into harmful agents. For example, some carcinogens, including polycyclic organic hydrocarbon components of soot and benzene, require metabolic activation from a ‘pro-carcinogen’ to the ‘ultimate carcinogen’.

All organs appear to have metabolic capability, often related both to organ function and to susceptibility to toxic agents. Understanding the specifics of the enzyme and enzyme families responsible for metabolism within cell types is important to the question of why chemicals have specific effects in specific organs.

In the case of benzene, about 50 per cent of the body burden is exhaled unchanged as the parent compound and the rest is metabolized to potentially toxic metabolites. Slowing down benzene metabolism leads to an increase in the relative amount that is exhaled rather than metabolized, and thus a decrease in bone marrow toxicity. An apparent genetically determined increase in benzene metabolism to toxic metabolites, or a decrease in the detoxification of these metabolites, increases haematological risk in humans—with both polymorphisms together appearing to be at least additive and perhaps multiplicative in increasing risk (Rothman et al. 1997; Kim et al. 2007). The application of genomics and proteomics to metabolism is often known as ‘metabolomics’.

Excretion

Excretion from the body can occur through a variety of different routes, primarily the gastrointestinal tract for unabsorbed compounds and for compounds dissolved in bile; and via the renal tract in urine for water-soluble agents of appropriate molecular weight and charge. Significant loss of volatile compounds can occur through the respiratory tract. Other routes of excretion include sweating and lactation, the latter unfortunately putting the breastfed infant at risk.

Interactions in multiple and combined exposures

Many toxicological studies of absorption, distribution, metabolism, and excretion are performed for single chemicals. Yet in real-life exposures, multiple and combined exposures are the norm rather than the exception. For such situations, the possibility of additive or synergistic effects, or potentiation or antagonism of effects has to be considered.

For example, in terms of interaction, exposure to two organophosphate insecticides may cause a simple additive adverse effect. In the case of exposure to carbon tetrachloride and ethanol, or asbestos exposure and cigarette smoking the combined effects are synergistic. The hepatotoxic effect of carbon tetrachloride can be potentiated by concurrent exposure to isopropanol (which by itself does not cause hepatotoxicity).

Antagonism could take various forms. Functional antagonism is exemplified by the opposing functional effects of a combination of barbiturate and norepinephrine. An example of chemical antagonism is the addition of BAL (British anti-Lewisite) to inactivate metal ions through chelation. The principle of dispositional antagonism is utilized in the treatment of poisoning with charcoal, or by use of an emetic or a diuretic. Receptor antagonism is seen in the case of the treatment of morphine overdose with naloxone.

Risk assessment

Risk assessment has evolved from two separate streams of toxicological reasoning: (1) for toxic agents implicitly or explicitly assumed to have a threshold, and (2) for carcinogens. The safety assessment of chemicals developed from simplified approaches such as studies on laboratory animals in which the dose (expressed usually as mg/kg body weight) capable of killing 50 per cent of the

test animals (the LD_{50}); or the concentration (expressed as parts per million of the substance in air or water or other medium, i.e. the LC_{50}) were determined. This observed dose was used as a basis for extrapolating to permissible levels in humans, often using several tenfold 'safety factors'. These protective factors were based on the concern that humans could be more sensitive as a species than were laboratory animals; that there was a greater variability in sensitivity among humans than among genetically inbred laboratory animals all raised in a similar environment; and that there could be adverse non-lethal effects that should be avoided. A presumptive tenfold safety factor has been added specifically to protect children in recognition of their greater risk to certain chemicals compared to adults (National Research Council 1993).

The inherent assumption in the 'safety factor' approach is that there is a threshold dose level below which there are no adverse effects. However, for carcinogenesis a single mutation could be the basis for the entire cancer process. As each molecule of a carcinogen at least theoretically could cause this mutation, a threshold could not be assumed, and, as a simplification, there is no level of exposure that is without risk.

Almost all DNA damage is repaired by efficient cellular processes. Some unrepaired mutations are lethal to the cell. As dead cells do not reproduce this cannot be the basis for cancer or for inherited abnormalities. The majority of mutations are silent in that they have no discernible effects. Accordingly, the risk of any one molecule actually causing cancer is infinitesimally small—literally trillions of molecules of carcinogens are inhaled with every cigarette, yet not all cigarette smokers develop cancer. The assumption that the risk is not zero has a major impact on communicating to the public about cancer risk due to chemical and physical carcinogens.

There are circumstances in which cancer causation does depend upon exceeding a threshold level of a chemical (e.g. the mechanism by which saccharin causes bladder cancer in laboratory animals appears to proceed through the precipitation of saccharin in the bladder which requires a dose sufficient to exceed the physico-chemical processes determining saccharin solubility). However, the prudent management of cancer risk usually assumes that the carcinogen is 'guilty until proven innocent' of having no risk-free level. In essence, the burden of proof is on industry to demonstrate scientifically that their cancer-causing chemical does have a threshold.

The four major components of risk assessment and their definitions are shown in Box 7.5.2.

Box 7.5.2 Components of risk assessment

Hazard identification: the determination of whether a specific chemical or physical agent is causally linked to a specific end point of concern; that is, specificity, or the second law of toxicology.

Dose-response evaluation: the determination of the relation between the magnitude of exposure and the probability of occurrence of the specific end point of concern; that is, the dose makes the poison, or the first law of toxicology.

Exposure evaluation: the determination of who and how many people will be exposed; through which routes; and the magnitude, duration, and timing of the exposure.

Risk characterization: the description of the nature and often the magnitude of the human risk, including attendant uncertainty.

Hazard identification

Hazard is the potential to cause harm. It is an intrinsic property of a substance or situation. Risk is the likelihood of harm occurring (and the severity of the resulting effect). It is a function of both hazard and exposure; for example, asbestos fibres sealed in a ceiling of an office have the potential to cause health effects, but the likelihood of that occurring is low if the ceiling is left intact. However, if the ceiling is demolished and dust containing the asbestos fibres is released, the risk to health can be considerable. The risk has changed because of the circumstances of exposure. The identification of the presence of a hazard is just one step in risk assessment; the subsequent steps such as exposure evaluation are key to determining what preventive action needs to be taken to reduce the risk.

A weight of evidence approach is often used by regulatory and quasi-scientific bodies to identify a hazard. In essence, a panel of scientists is asked to judge whether sufficient evidence exists to identify an agent or condition as having a risk of a specific effect in humans, or in some other target such as an ecosystem. The US approach to permitting the marketing of a new chemical is to have an internal Environmental Protection Agency scientific group review the chemical structure and other data submitted by industry. Similarly, the US Food and Drug Administration relies heavily on an advisory committee process to review evidence of efficacy and toxicity before approving a new pharmaceutical agent or medical device.

Formal weight-of-evidence approaches have been particularly useful in evaluating potential human carcinogens. The International Agency for Research on Cancer (IARC) of the World Health Organization categorizes carcinogens using this approach. IARC convenes expert panels to evaluate the evidence for carcinogenicity of specific chemical compounds or defined mixtures (e.g. diesel fuel, wood dust). The effort is focused on the weight of the evidence for carcinogenicity based upon carefully framed criteria considering animal toxicology, epidemiology, mechanistic information, and exposure data—but not on the potency of the compound as a cancer-causing agent. IARC has increased the weight it places on understanding toxicological mechanisms in assigning its score (Cogliano 2004). The information produced by IARC is used by many countries to decide governmental regulatory approaches at the workplace or general environment. In the United States, the IARC listing of carcinogens has no official status but carries much weight with US regulators as does a similar process used by the National Toxicology Program for its semi-annual Report on Carcinogens (National Toxicology Program 2011).

Relatively few chemicals have been reported as capable of causing cancer in humans. Of the perhaps 70,000–100,000 chemicals in commerce, about 100 are known to be human carcinogens. To an extent this represents the success of environmental health science in providing tools that guide chemical manufacturers away from new chemicals that are potentially carcinogenic. Early application in the chemical development process of simple test batteries evaluating the potential for mutagenesis or other predictors of cancer causation provides a responsible chemical industry with the means to avoid producing carcinogens or other potentially harmful products—and the means to avoid the regulatory and toxic tort consequences of harming the public. The value of this primary preventive approach depends upon the availability of effective toxicological test batteries. Such tests are based upon a basic understanding of the chemical

and biological processes underlying toxic effects. Unfortunately, the investment in using standardized test batteries for high production volume chemicals, and the major increase in such investments due to the new requirements such as the EU REACH legislation (see later) has not been accompanied by recognition of the need to develop better and more effective tests to protect the public. Advances in molecular toxicology provide many opportunities to improve these test batteries (National Research Council 2007).

Dose–response evaluation

The key issues in dose–response evaluation involve how to extrapolate from the high doses at which an effect is observed in an animal or epidemiological study, to the usually much lower levels of risk which are of public or policy concern. Crucial to extrapolation are assumptions about the shape of the dose–response curve, that is, threshold, linear non-threshold, sublinear, or supralinear. It must be emphasized that the levels of risk desired by our society, for example, in the range of less than 1 in 10,000 to less than 1 in 1 million lifetime, are usually too low to be scientifically verifiable. This is particularly true as the end points of concern cannot be solely attributed to the environmental hazard under consideration, as illustrated in Box 7.5.3.

Box 7.5.3 Case study: benzene and leukaemia in the United States

Based upon extrapolation from both epidemiological and animal studies, the potency of benzene is estimated to result in a range of 2.2–7.8 in 1 million increase in the lifetime risk of leukaemia of an individual who is exposed for a lifetime to 1 microgram/m³ benzene in air (US Environmental Protection Agency 2007).

In the case of the United States, a reasonable average benzene outdoor level is approximately 3 micrograms/m³, which would predict a risk of 6.6–23.4 in 1 million lifetime caused by this benzene exposure. Regulatory approaches that decrease that outdoor background level by two-thirds to 1.0 micrograms/m³ benzene nationwide would be estimated to decrease the risk of benzene-induced leukaemia by two-thirds. This would mean that nationwide there would be 4.4–15.6 less cases of leukaemia lifetime for every 1 million Americans, or approximately 10 in 1 million lifetime. Assuming a 70-year lifetime, and 350 million Americans, one can estimate that there would be 50 fewer cases of leukaemia a year nationwide as a result of a two-thirds decrease in outdoor benzene levels. This is a very small percentage of the 48,610 new cases of leukaemia in 2013 (<http://www.cancer.gov/cancertopics/types/leukemia>) estimated by the National Cancer Institute. While preventing that number of leukaemia cases is socially desirable, there are no current epidemiological or animal toxicology methods that could scientifically validate these assumptions.

A further complication is that for most of the US population, unregulated and highly variable indoor exposure to benzene, as well as to many other volatile organic compounds, far exceeds outdoor exposure. In fact, the major reason for a decrease in personal benzene exposure in the United States has been the decline in cigarette smoking for smokers, and its restriction from public places for non-smokers (Goldstein et al. 2011).

Exposure evaluation

Exposure evaluation is central to the management of environmental risks. Prevention of human exposure to a harmful chemical is synonymous with reduction of human risk. New advances in the field of exposure science are particularly crucial to understanding aggregate and cumulative risk (International Life Sciences Institute 1999; US Environmental Protection Agency 2003). Aggregate risk takes into account the different pathways of exposure for the same chemical. Cumulative risk describes the multiple effects of different agents through different routes, in essence an assessment of the impact of the mix of external synthetic and natural chemicals in which we all live. Cumulative risk assessment is particularly pertinent to environmental justice considerations.

The importance of exposure assessment in understanding risk is exemplified by investigations of potential adverse health consequences resulting from man-made events such as the attack on the World Trade Center in New York in September 2001, or natural disasters such as the earthquake and tsunami that destroyed the Fukushima nuclear plant in March 2011. Careful evaluation of disease end points in relation to exposure will help unravel the highly political and litigious issue of whether responders or the general public have an increased incidence of disease from such exposures generated by the explosion or in the process of cleaning up. New protocols and tools to assess exposures resulting from man-made or natural disasters may help in better evaluation of the exposure–effect relationship (Lioy et al. 2006).

Risk characterization

Many challenges are presented through the seemingly straightforward process of characterizing the risk estimated through the hazard identification, dose–response evaluation, and exposure evaluation steps. First, those doing the characterization are given an opportunity to put their ‘spin’ on the findings, for example, the public is likely to respond differently to the characterization that something is ‘99 per cent free of risk’ than to the numerically equivalent characterization that there is a ‘1 per cent likelihood of a serious consequence including death’.

There is also the challenge of characterizing who is at risk (the denominator). Reporting the risk in terms of the entire exposed general public can trivialize the risk to a highly sensitive subpopulation, such as asthmatics.

Risk can also be displaced from one country to another, as was observed when the dumping of hazardous waste, illegally sent from Europe to the Côte d’Ivoire, was reported to have caused 9000 acute illnesses and six deaths in Abidjan (Greenpeace 2006, 2012). Compounding the issue is that the Côte d’Ivoire, not having its own expertise, had to use its scanty funds to hire a European company to retrieve, ship, and process the toxic waste (United Nations Environmental Programme 2006). The European company involved in the incident made a series of payments to the Ivorian government and individual claimants in relation to the case without admitting liability. In July 2010, the company was found guilty of illegally exporting toxic waste from Amsterdam and concealing the nature of the cargo by a Dutch court. The company was fined 1 million euros (BBC 2012).

There is also a long-standing debate on the extent to which numerical uncertainty, rather than a simple qualitative statement

of the major sources of uncertainty, should be a routine part of risk characterization. Those in favour of routinely providing numerical boundaries that quantify the extent of uncertainty point out that the many estimates and default assumptions in a risk assessment provide wide ranges of uncertainty that should be presented to the risk manager and the general public.

Those in favour of a more restricted use of quantitative uncertainty analysis point out that most risk assessments are scoping activities aimed at considering alternatives or developing priorities. Further, major societal decisions are made on numerical estimates for which no uncertainty factors are given (e.g. the gross domestic product, unemployment estimates). The qualitative issues underlying uncertainty in a risk analysis should always be transparent to the risk manager and to the affected stakeholders.

The future of risk assessment

Risk assessment as a formal process to evaluate environmental agents has been evolving, particularly during the last few decades where more sophisticated approaches to cancer risk assessment and to cumulative and aggregate risk have developed. Using molecular toxicology to replace standard default assumptions is particularly promising (National Research Council 2007). Just as in other natural sciences, newer advances in data handling and informatics provide the opportunity to assess larger and more complex databases. Advances in epidemiologic methodology using biological indicators of exposure and effect based upon ecogenetics and other molecular biological techniques should be particularly fruitful (Omenn 2000). Conceptually, our genetic make-up is what loads the gun—but it is the environment that pulls the trigger. Identification of subpopulations sensitive to environmental factors will challenge regulatory and legal interpretation of the many environmental health laws that are aimed at protecting susceptible populations. Global harmonization of risk assessment has been under way for decades and will particularly be needed to avoid the use of environmental health principles as a façade for trade barriers. The application of evidence-based approaches to toxicology as is now increasingly used in medicine is a welcome development. It will be a challenge to use such processes for risk assessments that depend heavily on extrapolation to levels of risk below those that are readily observable, that is, the evidence will be indirect.

The regulatory approach to protecting worker health from toxic chemicals is often based upon both a measurable workplace standard and a subtle measure of effect. Thus for benzene, there is a 1 part per million, 8-hour time-weighted average workplace air standard as well as a requirement for routine blood counts. The latter informs the former both in terms of whether unmeasured exposures may be occurring, and whether a reconsideration of the allowable external standard is needed. As red cell, white cell, and platelet counts can be affected by a variety of common conditions, for example, infections and iron-deficiency anaemia, surveillance findings must be carefully evaluated before ascribing any observations to benzene exposure. In contrast, environmental standards are almost always measures of external pollutant emissions or ambient levels. Such standards are surrogates for the desired goal of avoiding adverse consequences to human health and the environment. Achieving a level of scientific knowledge that would permit the direct evaluation of subtle biological precursors of adverse effects would be a desired route to develop emission standards that

are truly protective. There is much work in progress in this field of environmental health indicators.

Human history of protecting against the consequences of environmental agents in essence is the history of catching up on the adverse effects of otherwise beneficial new technology—starting with the human use of fire. One of the more challenging new technologies with potential for beneficial and adverse consequences is that of nanotechnology. Decreasing the size of particles can result in unexpected new physico-chemical properties, in part due to a very high surface-to-volume ratio (Helland et al. 2007). Concern has been expressed as to what nano particles may do at the cellular level. The debate is unresolved about whether current toxicological testing schemes and regulatory processes are adequate to protect against the potential harm of nanotechnology products. However, toxicological principles are still relevant and central to the risk assessment process, as shown in Box 7.5.4.

The precautionary principle and/or/ versus risk assessment

A key issue facing risk management is how to proceed in the presence of hazard data with limited or no evidence of human toxicity. Application of the precautionary principle could be one approach for such an issue while additional scientific information is being gathered.

Box 7.5.4 Case study: potential environmental health effects of nanosilver

An area of concern identified by scientists has been the release of nanomaterials in consumer products to the environment. Nanosilver is one such product which has been used for treating socks that are marketed as non-odour producing as it confers antimicrobial properties. Benn and Westerhoff (2008) reported that six types of nanosilver treated socks leached silver nanoparticles when soaked in distilled water. This study raised concerns that nanosilver released from consumer products may enter wastewater systems and disrupt aquatic ecosystems. While ionic silver is known to be toxic to aquatic life, it is known that the speciation of silver affects its toxicity. Silver that is bound to sulphur or organic ligands is very much less toxic than free Ag ions. The alpha phase of silver sulphide, $\alpha\text{-Ag}_2\text{S}$ (found in nature as the mineral acanthite) is one of most insoluble Ag minerals known, in contrast to metallic Ag nanoparticles which are an efficient source of Ag ions in water.

In the environment, sources of silver can be from industry (e.g. mining, photographic, electronic) or from consumer products containing silver and nanosilver. In water, there could be dissolved Ag ions, bound Ag, Ag nanoparticles, coarser particles, and compounds, for example, AgCl_2 . During the process of waste water treatment, the silver is converted mainly to the insoluble alpha phase of silver sulphide ($\alpha\text{-Ag}_2\text{S}$). However, what happens to the silver when it is discharged into the natural waterways is still unknown. It is uncertain whether surface modifications and coatings of Ag engineered nanoparticles make it more mobile and resistant to transformation reaction and produce less $\alpha\text{-Ag}_2\text{S}$ formation (Nowack 2010).

The precautionary principle was given impetus by the 1992 Rio Declaration on the Environment and Development which provided the following statement (United Nations Environmental Programme 1992): 'In order to protect the environment, the precautionary approach shall be widely applied by States according to their capabilities. Where there are threats of serious or irreversible damage, lack of full scientific certainty shall not be used as a reason for postponing cost-effective measures to prevent environmental degradation.' The Rio Declaration statement includes qualifying language such as 'according to their capabilities' and 'postponing cost-effective measures'. Furthermore, the triple negative notion—that the *absence* of rigorous proof of danger does *not* justify *inaction* is viewed by some as rather weak (World Commission on the Ethics of Scientific Knowledge and Technology 2005). The statement forces the consideration of precautionary intervention but does not necessarily require such intervention.

There are many variants of this definition and an extensive literature devoted to developing a more rigorous definition of the precautionary principle. To some, the precautionary principle is merely a means to build more public health protection into quantitative risk analysis, with additional prudent defaults and safety factors to protect at risk populations, and a further focus on uncertainty. To others, the precautionary principle is a new way of addressing environmental risk and for dealing with complexity and uncertainty. Its use is more likely to provide timely and preventive interventions (Tickner and Ketelson 2001; Martuzzi 2007). Some of the important approaches advocated by the precautionary principle, such as transparency and involvement of stakeholders, have also been advocated by many under the rubric of risk assessment and management.

A working definition of the precautionary principle has been proposed by UNESCO (World Commission on the Ethics of Scientific Knowledge and Technology 2005; *italics in the original*) (Box 7.5.5). This includes the firm statement that actions based upon the precautionary principle should be subject to continuous analysis and review.

In addition to definitional issues, a number of major concerns have been raised about the precautionary principle. These are summarized in Box 7.5.6. First, what does the precautionary principle add to standard public health concepts? The precautionary principle is very welcome as an enthusiastic restatement of these concepts which provides an impetus and rallying point for actions that protect public health and the environment, even if nothing new is added to our understanding of the forces responsible for public health action and inaction.

The precautionary principle is said to be pertinent in situations where the scientific evidence is uncertain (Box 7.5.7). An often-cited example of this is the management of the health and environmental risks of endocrine disruptors, a particularly challenging problem in view of the need to consider the interactive effects of multiple chemicals with a wide range of additive, synergistic, and antagonistic interactions (Kortenkamp 2007). Yet it should be noted however, that the United States banned the production of polychlorinated biphenyls (PCBs) in 1976 despite the opposition, then and now, of industry on the grounds of uncertain science. The continual decline in body burdens of PCBs and dioxins have been accomplished based on regulatory decisions that were made without recourse to the precautionary principle. Advancing the science needed for decision-making must remain a major goal

Box 7.5.5 Working definition of the precautionary principle

'When human activities may lead to morally unacceptable harm that is scientifically plausible but uncertain, actions shall be taken to avoid or diminish that harm. *Morally unacceptable harm* refers to harm to humans or the environment that is

- ◆ threatening to human life or health, or
- ◆ serious and effectively irreversible, or
- ◆ inequitable to present or future generations, or
- ◆ imposed without adequate consideration of the human rights of those affected.

The judgment of *plausibility* should be grounded in scientific analysis. Analysis should be ongoing so that chosen actions are subject to review.

Uncertainty may apply to, but need not be limited to, causality or the bounds of the possible harm.

Actions are interventions that are undertaken before harm occurs that seek to avoid or diminish the harm. Actions should be chosen that are proportional to the seriousness of the potential harm, with consideration of their positive and negative consequences, and with an assessment of the moral implications of both action and inaction. The choice of action should be the result of a participatory process.'

Box 7.5.6 Questions about the precautionary principle

What does it add to standard public health concepts?

Is it true that complex scientific questions are unsolvable and, if so, is the precautionary principle needed to act in the face of scientific uncertainty?

In view of its alleged use to justify trade barriers, is it still possible to advocate the precautionary principle as an antidote to biased decision-making?

for environmental public health, including actions taken under the precautionary principle (Foster et al. 2000; Goldstein and Carruth 2003a, 2003b; Grandjean et al. 2004).

An example that may provide practical insight into the often confusing debate about the precautionary principle versus risk assessment is how the European Union (EU) and other countries evaluate the safety of chemicals. The EU promulgated the Registration, Evaluation, Authorisation and Restriction of Chemical Substances (REACH) regulations, after much debate, with its proponents focusing on the precautionary principle as a rationale for the new legislation. REACH requires industry to develop data, assess risk, and provide information about virtually all chemicals in use, including constituents of product mixtures. No distinction is made between newly developed chemicals or those long available in commerce—a contrast with the US Toxic Substances Control Act whose weakness in this regard has led to the inadequate testing of compounds such as the gasoline additive—methyl tert-butyl ether (MTBE) before its

Box 7.5.7 Case study: the precautionary principle and bisphenol A

Worldwide, over 3 million tons of bisphenol A (BPA) are produced annually. BPA can be found in many consumer products. These include reusable water bottles, baby bottles, implantable medical devices, and dental sealants. BPA is also a component of epoxy resins, which are used to overlay the inside of food and beverage cans, in cardboard and papers used for food wrapping, in some plastic water pipes, and in paints and cigarette filters. Of concern is the fact that BPA leaches out from these consumer products, even under normal use conditions. The leaching is increased under high temperatures, and with exposure to acidic or basic solutions.

Animal studies have shown that BPA may alter male and female reproductive tract development, the brain, and the mammary glands. In large-scale human population studies in various parts of the world, BPA has been detected in urine, blood, saliva, breast milk, and tissues and fluids associated with pregnancy at levels similar to those that have been shown to cause damage in animals.

In Canada, a study of over 5000 people showed that over 90 per cent had detectable levels of BPA in urine, with a geometric mean concentration of 1.16 ng/mL (Bushnik et al. 2010). Health Canada has stated that precaution is warranted, since it is not possible to dismiss the potential harmful effects of bisphenol A (Health Canada 2010). With this statement, Canada is the first country to declare BPA a health hazard, but additional regulatory action has yet to be taken (Vandenberg 2011).

inappropriate release into the environment (Goldstein and Erdal 2000).

The cost of implementing REACH is estimated at about US\$3–6 billion over the first 11 years for obtaining data and registering compounds. Risk assessment, based on both toxicity and exposure, is used extensively throughout the process, including setting priorities for data needs and making decisions on regulatory approaches. Unfortunately, there appears to be no uniform coordinated effort to develop the research where toxicological data is scant.

Unfortunately, the precautionary principle has been tainted through disagreements on its application. The United States, Canada, and other countries have disagreed with the EU on the extent of risk to health from consumption of hormone-treated beef or genetically modified foods. The EU's use of the precautionary principle to establish a stringent aflatoxin standard to the detriment of exports of sub-Saharan countries has been criticized as the misuse of public health principles for trade protectionism (Goldstein 2007). The risk of exposure to electromagnetic fields from use of mobile phones is another contentious and confused issue resulting in advice based on a mix of the precautionary principle and on the scientific evidence.

The primary missing ingredient in the approach to ever more complex environmental challenges, including such broader issues as global warming, is a systems-based approach incorporating the best science focusing on the most important questions. Unfortunately, the fragmented national and international approaches to environmental issues are producing piecemeal efforts that are falling further behind in protecting public health and the environment. Perhaps the need to respond to the

challenges of global climate change will lead to a more systematic and coordinated international effort.

Conclusion

Understanding the web of environmental cause and effect relations is an increasing challenge in a shrinking globe. Advances in toxicology, filtered through an appropriate appreciation of the optimal approaches to analyse and present risks to an involved public, are crucial to protecting public health and the environment.

Risk perception and communication

Baruch Fischhoff

Introduction to risk perception and communication

Sound health risk decisions require understanding the risks and benefits of possible actions. Some of those choices are personal. They include whether to wear bicycle helmets and seat belts, whether to read and follow safety warnings, whether to buy and use condoms, and how to select and cook food. Other choices are made as citizens. They include whether to protest the siting of hazardous waste incinerators and halfway houses, whether to support fluoridation and 'green' candidates, and what to include in sex education.

Sometimes, single choices have large effects (e.g. buying a safe car, taking a dangerous job, getting pregnant). Sometimes, small effects accumulate over multiple choices (e.g. exercising, avoiding trans-fats, wearing seatbelts, using escort services). Sometimes, health-related choices focus on health; sometimes, they do not (e.g. purchasing homes that require long commutes, choosing friends who exercise regularly, joining religious groups opposed to vaccination).

This chapter reviews the research base for assessing and improving individuals' understanding of the risks and possible benefits of health-related choices. Following convention, these pursuits are called *risk perception* and *risk communication*, respectively, even though the same basic behavioural principles apply to the benefits that all risk decisions entail, if only the benefits of reducing risks (Fischhoff et al. 2011). Psychologists sometimes reserve the term 'perception' for direct physiological responses to stimuli, using 'judgement' for the translation of those responses into observable estimates. A perennial research topic is identifying the conditions under which judgement surrenders to perception, and when emotions play little role because people know what they want to do (Slovic et al. 2005). This chapter emphasizes judgement, hoping to expand the envelope of deliberative processes in personal and public health decisions.

Inaccurate judgements about risks can harm people. So can inaccurate beliefs about those judgements. If their understanding is overestimated, then people may face impossibly hard choices (e.g. among unfamiliar medical alternatives, without adequate counselling). If their understanding is underestimated, then people may be needlessly denied the right to choose. As a result, the chapter assumes: (1) that descriptive statements about people's beliefs must be underpinned by empirical evidence and (2) that evaluative statements about the adequacy of people's understanding must be

founded on rigorous analysis of what they need to know, in order to make a sound decision. To these ends, the chapter emphasizes methodological safeguards against misguided assessments.

The next section, 'Quantitative assessment', considers beliefs about how large risks are. The following section, 'Qualitative assessment', treats beliefs about the processes that create and control risks, on the basis of which people produce and evaluate quantitative estimates. Both sections address both measurement issues and barriers to understanding. The next section, 'Creating communications', provides a structured approach for developing communications about health-related decisions, focused on individuals' information needs. The 'Conclusion' section considers the strategic importance of risk communication in public health. Access to research on complementary social and emotional processes might begin with Breakwell (2007), Krinsky and Golding (1992), and Peters and McCaul (2005).

Quantitative assessment

Estimating risk magnitude

A common complaint among experts is that 'the public doesn't realize how small (or large) Risk X is'. There is empirical evidence demonstrating such biases (Slovic 2001). However, that evidence has often been collected in settings designed to reveal biases. Looking for problems is a standard strategy in experimental sciences, designed to reveal the processes creating those problems, but not their prevalence or magnitude in specific domains of everyday life. Generalizing from research decisions to real-world ones requires matching the conditions in each. Looking at the details of one widely cited study shows how that matching process might proceed, while introducing some general principles and results.

Participants

Lichtenstein et al. (1978) asked members of a civic group in Eugene, Oregon, to estimate the annual number of deaths in the United States from 30 causes (e.g. botulism, tornadoes, motor vehicle accidents). They were older than the college students often studied by psychologists. Age could affect *what* people think, as a result of differences in their education and life experience. It is less likely to affect *how* they think. Many cognitive processes are widely shared, once people pass middle adolescence, unless they suffer some impairment (Fischhoff 2008; Reyna and Farley 2006; Finucane and Gullion 2010).

Fig. 7.6.1 Best quadratic fit line to geometric mean judgements of the annual toll from 40 causes of death in the United States, compared to best available statistical estimates.

Reproduced from Fischhoff, B. and Kadavy, J., *Risk: A Very Short Introduction*, Figure 12, p. 92, Oxford University Press, Oxford, UK, Copyright © Baruch Fischhoff and John Kadavy 2011, by permission of Oxford University Press.

One widely shared class of cognitive processes relies on judgemental *heuristics* to infer unknown quantities (Kahneman et al. 1982; Gilovich et al. 2003). One well-known heuristic is *availability*, whereby people assess an event's probability by how easily instances come to mind. Although more available events are often more likely, media coverage (among other things) makes some events disproportionately available, thereby inducing biased judgements—unless people take into account how appearances can be deceiving. *How* people generate instances of events, using their memory and imagination, should reflect widely shared general cognitive processes. *What* those memories and images contain, as well as what faith people place in information sources, should vary with their experiences.

Lichtenstein et al. (1978) elicited judgements with two *response modes*. One asked people to pick the more frequent of two paired causes of death (e.g. asthma, botulism) and then to estimate the ratio of their frequencies. The second asked for the number of deaths, after providing the value for one cause (either electrocution or motor vehicle accidents) in order to give respondents a feeling for annual death rates—after pretests found that many people had little idea about what range of numbers to give. Fig. 7.6.1 shows results with the second method, which are typical of such studies.

Results

1. Judgements of the *relative* risk from different causes were similar however the question was asked. Risks assigned higher frequency estimates were typically judged more likely when paired with risks with lower frequency estimates. Ratios of the direct estimates were similar to directly estimated ratios. Thus, these people seemed to have an internal 'scale' of relative risk, which they expressed consistently even with these unfamiliar tasks.
2. Judgements of *absolute* risk, however, were affected by the procedure. People told that 50,000 people die annually from auto accidents gave estimates two to five times higher than did people told that 1000 die annually from electrocution. Thus, people seemed

to have less feeling for absolute frequency, rendering them sensitive to implicit cues given by how questions are posed (Poulton 1989; Schwarz 1999; Fagerlin and Peters, 2011).

3. Absolute risk judgements were less dispersed than were the corresponding statistical estimates. Although the latter varied over six orders of magnitude, individuals' estimates typically ranged over three to four. That 'compression' could reflect another judgemental bias, called *anchoring*, whereby judgements are drawn toward an initial value that draws their attention. With these anchors (electrocution, motor vehicle accidents), people overestimated small frequencies and underestimated large ones. That pattern might change with other anchors. For example, a lower anchor (e.g. botulism) should reduce (or perhaps eliminate) the overestimation of small frequencies, while increasing the underestimation of large ones.
4. Relative and absolute risk judgements seemed to reflect availability bias. Some causes of death (e.g. flood, homicide, tornadoes) received higher estimates than did others with similar statistical frequency. Typically, there were causes that were disproportionately reported in the news media. When told about the possibility of availability bias, participants could not improve their judgements, consistent with the finding that tracking frequency is such an automatic process that people do not realize how observations shape their perceptions (e.g. Koriati 1993).

Thus, Lichtenstein et al. (1978) found some response patterns that were affected by the procedure that was used (e.g. absolute estimates) and some that were not (e.g. relative risk judgements). A century of psychophysics research (Poulton 1989) has identified many other procedural details that can affect quantitative judgements. Determining how much those details affect any specific judgement requires studies examining their relative impact in that context. How important that effect (or any bias) is depends on the decision. Shifting fatality estimates by a factor of two to five might tip some decisions, but not others.

Fischhoff and MacGregor (1983) provide another example of response mode effects. They asked about the chances of dying (in the United States) among people afflicted with various maladies (e.g. influenza), in four ways: (1) how many people die out of each 100,000 who get influenza; (2) how many people died out of the 80 million who caught influenza last year; (3) for each person who dies of influenza, how many have it and survive; (4) 800 people died of influenza last year, how many survived? As in Lichtenstein et al. (1978), relative risk judgements were consistent across response modes, while absolute estimates varied greatly (over one to two orders of magnitude). They also found that people liked format (3) much less than the others—and were much less able to remember statistics reported that way. That format also produced the most discrepant estimates, identifying it as a poor way to elicit or communicate risks.

Evaluative standards

Risk judgements can be evaluated in terms of their *consistency* or their *accuracy*. Evaluating consistency requires asking logically related questions and comparing the answers (e.g. do risk estimates increase with increasing exposure?). Evaluating accuracy requires asking questions that are sufficiently precise to be compared to sound risk estimates (e.g. Chapter 7.5). Without sound scientific estimates, individuals' judgements may be compared to a

standard that they would reject. For example, after the 9/11 attacks in New York by terrorist-commandeered aeroplanes, some observers claimed that some Americans had increased their risk level by driving, rather than flying. These claims were based on historical risk statistics. However, it was difficult to ascertain the safety of aviation at that time as the US aircraft fleet was grounded, whereas the historical statistics used for driving encompassed all drivers, including the young, elderly, and drinkers, and were not specific to those drivers who had changed their transportation modes. Even if these historical statistics were valid, other factors must have affected the drivers' decisions such as the cost and hassle of flying during that period. As a general rule, one cannot infer risk judgements from risk decisions without knowing the other factors involved.

Probability judgements

The sensitivity of quantitative judgements to methodological details might suggest avoiding them in favour of verbal quantifiers (e.g. likely, rare). Indeed, some researchers hesitate to elicit probabilities at all, fearing that the questions will exceed laypeople's cognitive capabilities. That hesitation is strengthened by evidence of lay innumeracy (Fagerlin and Peters 2011). However, even imperfect measures can have value, if their strengths and weaknesses are understood. The research literature on eliciting probability judgements is vast (O'Hagan et al. 2006). Findings relevant to public health researchers and practitioners include:

1. People often prefer to provide verbal judgements and receive numeric ones, given that numeric responses require more effort and incur greater accountability (Erev and Cohen 1990).
2. Verbal quantifiers are often interpreted differently across people and situations (e.g. rare disease vs. rare sunny day), making it hard to know what those terms mean, in situations without established usage norms (Budescu and Wallsten 1995; Schwarz 1999).
3. People can use well-designed numeric scales as well as verbal ones. For example, Woloshin et al. (1998) found similar performance and satisfaction with linear and log-linear probability scales as with verbal ones.
4. Numeric probability judgements often have good *construct validity*, in the sense of correlating sensibly with other variables. For example, Fischhoff et al. (2000) found that teens who gave higher probabilities of becoming pregnant also reported more sexual activity; teens giving higher probabilities of getting arrested also reported more violent neighbourhoods.
5. Misinformation and mistaken inferences can bias probability judgements, as when one's own care in driving is more available than that of other drivers, making one feel safer than average.
6. Probability judgements can be deliberately biased, when people respond strategically. For example, Christensen-Szalanski and Bushyhead (1993) found that physicians overestimated the probability of pneumonia, fearing that unlikely cases might be neglected. Weather forecasters may overstate the probability of precipitation, in order to keep people from being caught unprotected (Lichtenstein et al. 1982).
7. Transient emotions can affect judgements. For example, anger increases optimism, fear the opposite (Lerner and Keltner 2001), with effects large enough to tip close decisions.
8. Judgements of the probability of being correct are moderately correlated with how much people actually know. For example, Fischhoff et al. (1977) had people choose the larger of two causes of death (from Lichtenstein et al. 1978), and then give the probability of having chosen correctly. In relative terms, people were correct more often when they were more confident. In absolute terms, *overconfidence* (e.g. being 90 per cent confident with 75 per cent correct choices) is typical with hard tasks, underconfidence with easy ones.
9. Probability judgements can vary by response mode (e.g. odds vs probabilities, probabilities vs relative frequencies, judgements of individual or grouped items) (Griffin et al. 2003).
10. Some numeric values are treated specially. For example, people seldom use fractional values; when uncertain what to say, people sometimes say 50 in the sense of 50–50, rather than a numeric probability (Bruine de Bruin et al. 2000).
11. Probability judgement processes mature by middle adolescence. For example, teens are no more likely than adults to believe in their own adolescent invulnerability (Quadrel et al. 1993); indeed, unlike adults, many teens greatly exaggerate their probability of premature death (Fischhoff et al. 2000).
12. People differ in their ability to use probabilities, with lower ability correlated with poorer performance on other tasks and with life outcomes that require decision-making competence (Bruine de Bruin et al. 2007b).
13. The use of probabilities can sometimes be improved with even a single round of prompt, intense feedback (Lichtenstein and Fischhoff 1980).
14. Experts' judgements are often imperfect, when forced to go beyond established knowledge and calculations (O'Hagan et al. 2006).

A test of any measure is its predictive validity. Even though risk decisions often involve choices among options with non-risk outcomes (which might outweigh risk concerns), Brewer et al. (2007) found that risk judgements alone have predictive value. Similarly, teens' probability judgements predict major events in their lives (e.g. pregnancy, incarceration), one to 5 years hence (Fischhoff 2008). Pointing to probability judgements that are higher than actual risks, some researchers have argued that public health communications have worked too well, producing exaggerated fears of smoking (Viscusi 1992) and breast cancer (Black et al. 1995).

Defining risk

Studies like Lichtenstein et al. (1978) measure 'risk' perceptions, if 'risk' means 'chance of death'. However, even among experts, 'risk' has multiple meanings (Fischhoff et al. 1984; National Research Council 1996). 'Risk' might mean just death or it might also include other outcomes, such as morbidity and trauma. Even if 'risk' only considers fatalities, it might be measured in terms of probability of death, expected life years lost, or deaths per person exposed (or per hour of exposure). Each definition entails an ethical position. For example, *probability of death* treats all deaths (and lives) equally, whereas *life-years lost* places extra weight on deaths of young people and from injury (e.g. drowning, driving, workplace hazards), as each incurs many lost years, compared to deaths from chronic illnesses. Adding morbidity and trauma would heighten concern

for alcohol and illegal drugs, which can ruin lives without ending them.

Without clear, shared definitions, people can unwittingly speak at cross purposes, when addressing 'risks'. Clarifying definitions has long been central to risk research. Before considering that research, it is worth noting that 'risky' (or 'safe') is sometimes used as a discrete variable, treating activities as risky (or safe) or not. Such shorthand says little, without defining the threshold of concern. Calls for 'safe' products can be unfairly ridiculed, if the demand for reasonable risk is equated with zero risk. Such demands are seen in the various *precautionary principles*, identifying risks seen as too great to countenance (DeKay et al. 2002). However, even those calls may be more about uncertainty than risk, reflecting aversion to hazards that science does not understand (Löfstedt et al. 2002).

Catastrophic potential

One early risk perception study asked experts and laypeople to estimate the 'risk of death' from 30 activities and technologies (Slovic et al. 1979). These judgements correlated more strongly with statistical estimates of average-year fatalities for experts than they did for laypeople. However, when asked to estimate 'fatalities in an average year', experts and laypeople responded similarly. Comparing the two sets of judgements suggested that lay respondents interpreted

'risk of death' as including catastrophic potential, reflecting the expected deaths in non-average years. If so, then experts and laypeople agreed about the risk of routine (average year) deaths (for which the science is often good), but disagreed about possible anomalies (for which the science is naturally much weaker). Thus, when experts and laypeople disagree about risks, they might be seeing the facts differently or they might be looking at different facts, ones relevant to their definition of 'risk' (National Research Council 1989). People might consider catastrophic potential because they care more about lives lost at once than lost individually or because catastrophic potential suggests hazards that might spin out of control (Slovic et al. 1984).

Dimensions of risk

Beginning with Starr (1969), many features, like uncertainty and catastrophic potential, have been suggested as affecting definitions of risk (Lowrance 1976). In order to reduce that set to a manageable size, Fischhoff et al. (1978) asked members of a liberal civic organization to rate 30 hazards on nine such features. Factor analysis on mean ratings identified two *dimensions*, which accounted for 78 per cent of the variance. Fig. 7.6.2 plots factor scores in this 'risk space'. Similar patterns emerged with students, members of a conservative civic organization, and risk experts, suggesting that

Fig. 7.6.2 Location of 30 hazards within the two-factor space obtained from members of a civic group who rated each activity or technology on each of nine features. Ratings were subjected to principal components factor analysis, with a varimax rotation.

people think similarly about such factors, even when they disagree about how specific hazards stack up.

Hazards high on the vertical factor (e.g. food colouring, pesticides) were rated as new, unknown, and involuntary, with delayed effects. Hazards high on the horizontal factor (e.g. nuclear power, commercial aviation) were rated as fatal to many people, if things go wrong. The factors were labelled *unknown* and *dread*, respectively, and might be seen as capturing cognitive and emotional aspects of people's concern.

Many studies following this 'psychometric paradigm' have found roughly similar dimensions, using differing elicitation modes, scaling techniques, items, and participants (Slovic 2001). When a third dimension emerges, it typically reflects the scope of the threat, labelled *catastrophic potential*. The position of hazards in the space correlates with attitudes towards them, such as how stringently they should be regulated. Analyses of mean responses, as in the figure, are best suited to predicting aggregate (societal) responses. Individual differences have also been studied (e.g. Vlek and Stallen 1981; Arabie and Maschmeyer 1988).

Risk comparisons

The multidimensionality of risk means that hazards similar on some dimensions can still evoke quite different responses. This fact is neglected in appeals to accept one risk because one has accepted another risk with some similarities (Fischhoff et al. 1984). A common kind of such 'risk comparison' presents the statistical risks from many hazards in common terms (e.g. arguing that people who eat peanut butter should accept nuclear power because both a tablespoonful of peanut butter and 50 years living by a nuclear power plant create a one-in-a-million risk of premature death). (For a summary of the problems with such risk comparisons, see National Research Council (2006).)

One way to improve the legitimacy of risk comparisons is to involve users in setting them. The US Environmental Protection Agency (1993) followed this strategy in facilitating dozens of regional, state, and national 'risk-ranking exercises', in which participants identified the dimensions important to them, then deliberated priorities, supported by technical staff providing relevant evidence. Letting participants choose the dimensions made their exercise more relevant, but reduced comparability across exercises. Florig et al. (2001) developed a method for standardizing such comparisons, based on the risk dimensions research (Table 7.6.1). The UK government has endorsed a variant (HM Treasury 2005).

Qualitative assessment

Event definitions

Once adequately defined, 'risk' can be estimated. For risk assessors, that means specifying such details as the frequency and timing of intercourse, contraceptives used, and partners' physical state—when estimating the risk of pregnancy. Two experts with different definitions may see the same data and produce different estimates. So may laypeople asked for their perceptions of risk, but forced to guess at what exactly is meant. Consider this question from a prominent national survey: 'How likely do you think it is that a person will get the AIDS virus from sharing plates, forks, or glasses with someone who has AIDS?' After answering this question, US college students were asked what they had inferred about the kind and amount of sharing. Most agreed about the kind, with 82 per cent selecting 'sharing during a meal' from a set of options. However, they disagreed about the frequency, with 39 per cent selecting 'a single occasion', 20 per cent 'several occasions', 28 per cent 'routinely', and 12 per cent uncertain (Fischhoff 1996). Respondents making different assumptions were, in effect, answering different questions, whose meaning researchers must guess, if they are to offer any conclusions about lay risk perceptions.

Laypeople are, similarly, left guessing when experts communicate about risks ambiguously (Fischhoff 1994). For example, McIntyre and West (1992) found that teens knew that 'safe sex' was important, but disagreed about what it entailed. Downs et al. (2004b) found that teens interpret 'it can only take once' as meaning that they will get pregnant after having sex once. If they do not, some infer that they are infertile, encouraging unsafe sex. Murphy et al. (1980) found people divided over whether '70 per cent chance of rain' referred to: (1) the area receiving rain, (2) the time it would rain, (3) the chance of some rain anywhere, or (4) the chance of some rain at the weather station (the correct answer). Fischhoff (2005a) describes procedures for making sure that experts and laypeople are talking about the same thing, when they communicate about risks.

Supplying details

The details that people infer, when given ambiguous and incomplete risk questions or messages, reveal their intuitive theories. For example, teens who thought aloud while judging the probabilities of ambiguous events (like that about sharing plates, etc., with someone with AIDS), noticed many unstated details, including ones that would affect scientific risk estimates (Fischhoff 1994). For example,

Table 7.6.1 A standard multidimensional representation of risks

Number of people affected	Degree of environmental impact	Knowledge	Dread
Annual expected number of fatalities: 0– 450 –600 (10% chance of zero)	Area affected by ecosystem stress or change 50 km²	Degree to which impacts are delayed 1–10 years	Catastrophic potential 1000 times expected annual fatalities
Annual expected number of person-years lost: 0– 9000 –18,000 (10% chance of zero)	Magnitude of environmental impact Modest (15% chance of large)	Quality of scientific understanding Medium	Outcome equity Medium (ratio = 6)

they wondered about the 'dose' of most risks (e.g. the amount of drinking and driving, when judging the probability of an accident), when it was missing from a question. An exception was not thinking about the amount of sex involved, when judging the risks of pregnancy and HIV transmission. Teens seemed to believe that an individual is either vulnerable or not, making the number of exposures immaterial. Sometimes they considered variables unrelated to risk, such as how well partners know one another. In order to dispel such misunderstanding, Downs et al. (2004a) explicitly addressed how partners could fail to self-diagnose sexually transmitted infections (STIs)—in an interactive DVD that successfully reduced adolescent sexual risks.

Cumulative risk—a case in point

There is no full substitute for directly studying the beliefs that people bring to and take away from risk messages, especially when recipients come from cultures and social circumstances different than those of the communicators. However, the research literature provides a basis for anticipating those beliefs (Fischhoff et al. 2011). For example, optimism bias is so widespread that one can assume that people see themselves as facing less risk than other people, whenever some personal control seems feasible. Similarly, teens' insensitivity to the amount of sex, when judging STI risks, reflects a well-known insensitivity to how risks accumulate over repeated exposures. Thus, people cannot be expected to infer the cumulative accident risk from repeatedly driving without a seat belt (Slovic et al. 1978) or the pregnancy risk from having sex without effective contraceptives (Shaklee and Fischhoff 1990). One corollary of this insensitivity is not realizing the cumulative impact of small differences in single-exposure risks (e.g. slightly better contraceptives, wearing a seat belt). People similarly underestimate exponential growth (e.g. Wagenaar and Sagaria 1975; Frederick 2005).

For example, Linville et al. (1993) had college students judge the probability of transmission from an HIV-positive man to a woman from 1, 10, or 100 cases of protected sex. For one case, the students' median estimate was 0.10, much higher than then-current public health estimates—despite using a log-linear response mode that facilitated expressing very low probabilities (Woloshin et al. 1998). The median estimate for 100 contacts was 0.25, a more accurate estimate, but much too small given their one-case estimates. Given the inconsistency in these beliefs, researchers studying risk perceptions must ask about both, in order to get a full picture, and educators seeking to inform risk beliefs need to communicate them both, in order to create a full picture.

Mental models of risk processes

The role of mental models

As mentioned, when people lack explicit information about the magnitude of a risk (or benefit), they must infer it. Judgemental heuristics, like availability, provide one class of inferential rules for deriving specific estimates from general knowledge. A second class of inferential rules draws on individuals' *mental models* of the general processes that create and control risks in order to estimate those risks, follow discussions about them, and generate choice options. The term 'mental model' refers to the intuitive theories supporting such inferences. Mental models have a long history in psychology, having been studied for topics as diverse as how people understand physical processes, international tensions, complex equipment, energy conservation, climate change, interpersonal

relations, and drug effects (Meyer et al. 1985; Ericsson and Simon 1993; Sterman and Sweeney 2002).

However sound these inferences, they can produce erroneous conclusions when mental models contain flawed assumptions (or 'bugs'). For example, not realizing how quickly the risks of pregnancy and STIs accumulate over sex acts could make other knowledge seem irrelevant. Bostrom et al. (1992) found that many people knew that radon was a colourless, odourless, radioactive gas, but overestimated its risks because they also thought that radioactivity meant permanent contamination. However, radon's by-products (or 'progeny') have short half-lives, meaning that once intrusion of the gas stops, the problem disappears. However, while it persists, rapid decay means rapid energy release. Homeowners unaware of these facts might reasonably decide not to test for radon—the problem doesn't seem urgent and there is nothing to do anyway if they find a problem.

Morgan et al. (2001) offer a general approach appropriate to studying mental models for complex, uncertain processes, like those of many public health risks. The approach begins by creating a formal (or 'expert') model, summarizing relevant scientific knowledge, with enough conceptual precision to allow computing quantitative predictions, were its data needs met (Fischhoff et al. 2006). A common formalism is the influence diagram (Howard 1989). Fig. 7.6.3 shows such a diagram for radon. An arrow means that the value of the variable at its head depends on the value of the variable at its tail. Thus, the lungs' particle clearance rate depends on individuals' smoking history. Other examples include STIs (Fischhoff et al. 1998), breast implants (Byram et al. 2001), sexual assault (Fischhoff 1992), Lyme disease, falls, sexual assault, breast cancer, vaccination, infectious disease, and nuclear energy sources in space (Morgan et al. 2001; Fischhoff 2005b; Downs et al. 2008).

The research continues with open-ended one-on-one interviews, structured around the model, eliciting lay beliefs in their intuitive formulation. Those 'mental model' interviews begin with general questions, asking respondents what they believe about the topic, then to elaborate on each issue raised. The interviews are non-judgemental, seeking to understand, not evaluate respondents' perspectives. After exhausting responses to general questions, interviewers ask increasingly pointed ones, starting with general processes (e.g. exposure, effects, mitigation), and proceeding to specific issues (e.g. 'How does the amount of sex (or number of partners) affect HIV risk?'; 'What does 'safe sex' mean?'). A variant has people think aloud while sorting photographs by their relevance, hoping for insights into topics that were otherwise missed. For example, seeing a supermarket produce section prompted some respondents to say that radon might contaminate plants (Bostrom et al. 1992).

Once transcribed, interviews are coded into the formal model, adding new elements raised by respondents, marked as either misunderstandings or expertise (e.g. knowledge about how equipment really works). The precision of the formal model typically allows reliable coding. Once mapped, lay beliefs can be analysed in terms of their accuracy, relevance, specificity, and focus. Coding for accuracy can reveal beliefs that are correct and relevant, wrong, vague, peripheral, or general (e.g. radon is a gas). For example, Bostrom et al. (1992) found that most respondents, drawn from civic groups, knew that radon is a gas (88 per cent), which concentrates indoors (92 per cent), is detectable with a test kit (96 per cent), comes from underground (83 per cent), and can cause cancer

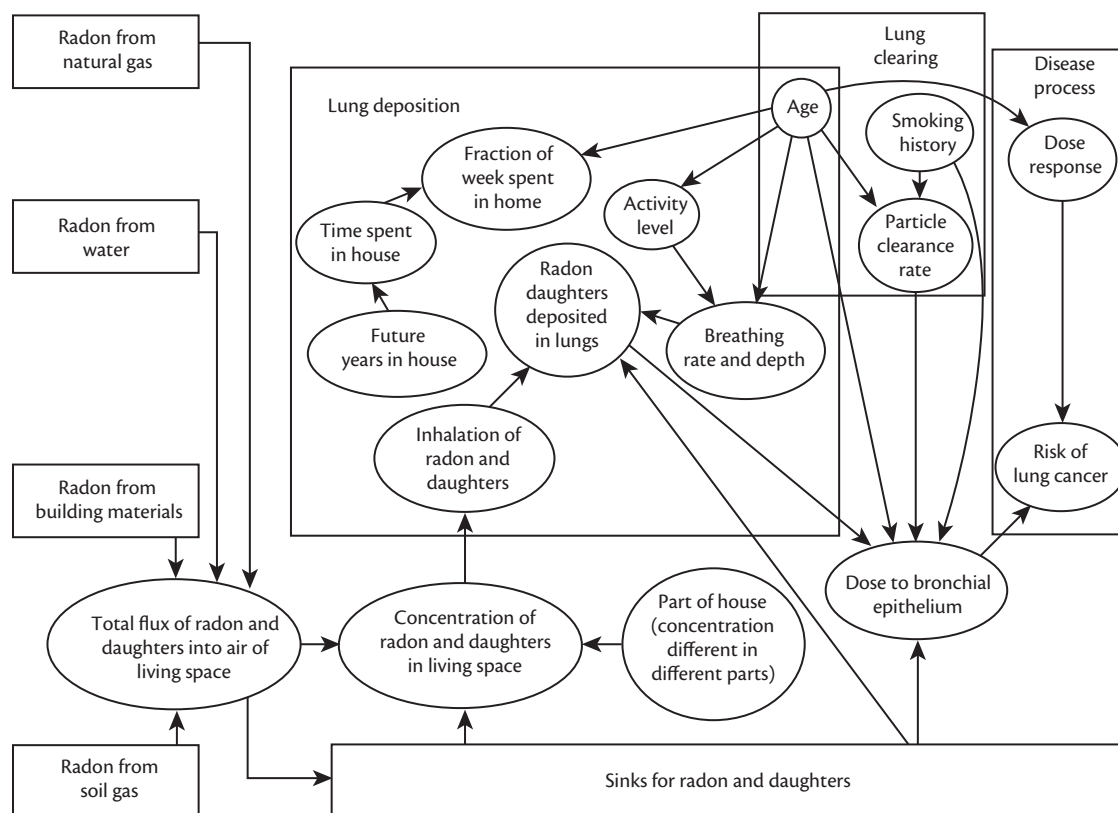

Fig. 7.6.3 Expert influence diagram for health effects of radon (in a home with a crawl space). This diagram was used as a standard and as an organizing device to characterize the content of lay mental models.

(63 per cent). However, many also believed erroneously that radon affects plants (58 per cent), contaminates blood (38 per cent), and causes breast cancer (29 per cent). Few (8 per cent) mentioned that radon decays. The interviews led to a structured survey suited to assessing the prevalence of beliefs in larger samples, with questions having ecological validity, in the sense of sampling the key topics in the formal model (Bruine de Bruin et al. 2007a).

From risk beliefs to risk decisions

The adequacy of risk perceptions depends on the decisions that depend on them. Some decisions require precise estimates, others just a rough idea. For example, von Winterfeldt and Edwards (1986) showed that many decisions with continuous options (e.g. invest US\$X) are insensitive to the precise values assigned to the probabilities and utilities of possible outcomes. Dawes et al. (1989) showed that choices with discrete options (e.g. choosing graduate candidates) are often insensitive to exactly how predictors or outcomes are weighted, meaning that simple linear (weighted-sum) models may do as well as more complicated ones. Thus, any model that considers the probability and magnitude of consequences should have some success in predicting behaviour, if researchers have some idea about the topics on decision-makers' minds. On the other hand, because many such models will do reasonably well, they provide little insight regarding the underlying processes.

Feather (1992) provides a general account of such *expectancy-value* (probability-consequence) models, which predict decisions

by multiplying ratings of the likelihood and desirability of potentially relevant consequences. The health-belief model and the theory of reasoned action fall into this general category. For example, Bauman (1980) had seventh graders rate the importance, likelihood, and valence (positive or negative) of 54 possible consequences of using marijuana. A 'utility structure index', computed from these three judgements, predicted about 20 per cent of the variance in respondents' reported marijuana usage.

The template for studying these perceptions is a *decision tree* with the options, relevant outcomes, and uncertain events linking the two. Fig. 7.6.4 shows a simple decision tree, for men considering the dietary supplement, saw palmetto, for symptomatic relief of benign prostatic hyperplasia. The choice (the square node on the left) leads to a sequence of events (the circular *uncertain event* nodes), resulting in the outcomes (or consequences) on the right. The success of a structured model (e.g. Bauman 1980) depends on how well it captures the issues that occupy decision-makers. In identifying those elements, researchers can draw on previous research, convention, or intuitions—or by eliciting them from decision-makers. The greater the social distance between the experts and the decision-makers, the more important such elicitation becomes—lest experts miss options, uncertainties, or outcomes that occupy decision-makers, but would never occur to them, or vice versa.

Effective elicitation typically requires prompting different ways of looking at a decision, so that respondents do not get locked into a narrower perspective than would occur in life (Schwarz 1999).

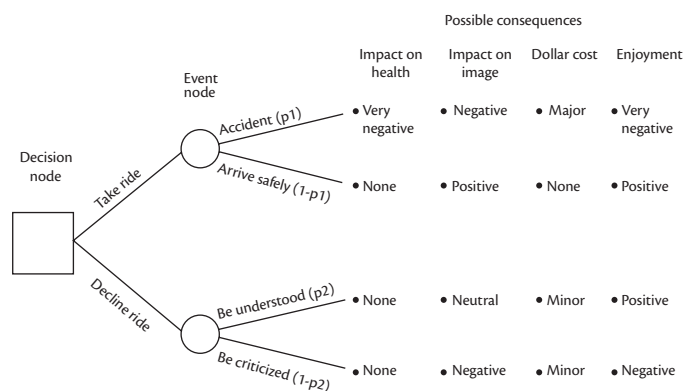

Fig. 7.6.4 A simple decision tree for whether to take saw palmetto for benign prostatic hyperplasia.
Reproduced From Fischhoff, B. and Quadrel, M.J. Adolescent alcohol decisions, *Alcohol Health and Research World*, Volume 15, pp. 43–51, 1991.

For example, Beyth-Marom et al. (1993) had teens work out possible consequences of either accepting a risky option (e.g. drinking and driving, smoking marijuana) or rejecting it. Although accepting and rejecting are formally complementary actions, they can stimulate different thought processes. In this study, participants who thought about accepting risky options produced more consequences (suggesting that action is more evocative than inaction), a higher ratio of bad to good consequences (suggesting that risks are more available from that perspective), and fewer references to social consequences (suggesting that social pressure is more salient when resisting temptation than when yielding to it). When participants thought about making choices repeatedly, rather than just once, they often produced different consequences (e.g. repeatedly 'accepting an offer to smoke marijuana at a party' evoked more mentions of social reactions than did thinking about doing it once). Parents of these teens cited similar possible outcomes, except for being more likely to mention long-term consequences (e.g. ruining career prospects). From this perspective, if parents and teens see the choices differently, it is not because they see different outcomes as possible, but because they disagree about how likely and important those outcomes are. These different perspectives would be hidden with structured surveys that elicit ratings of fixed, predetermined consequences.

Fischhoff (1996) reports a study imposing even less structure, with 105 teens asked to describe three difficult personal decisions in their own words. These descriptions were coded in terms of their content (which choices trouble teens) and structure (how they were formulated). For example, none of the teens mentioned a choice about drinking-and-driving, while many described drinking decisions. Few of their decisions had option structures as complicated as Fig. 7.6.4. Rather, most had but one option (e.g. whether to attend a party with drinking). Judging by Beyth-Marom et al.'s (1993) results, teens looking at that option saw different decisions than did teens focusing on other possible options (e.g. going somewhere else) or multiple options. Experimental research has found that the opportunity costs (foregone benefits) of neglected options are less visible than are their direct consequences (Thaler 1991). For example, the direct risks of vaccinating children can loom

disproportionately larger than the indirect risks of not vaccinating them (Ritov and Baron 1990).

Different methods for eliciting decision-makers' perspective have different, often complementary strengths and weaknesses (Ericsson and Simon 1993). Structured methods (e.g. surveys) can omit important aspects of decisions or express them in unfamiliar terms. Open-ended methods (e.g. mental models interviews) allow people to say whatever is on their minds in their own terms, but require tight control lest researchers influence what is said. Combining methods can provide a rounded picture, especially when a formal analysis ensures their comprehensiveness. Unlike commercial research, scientific studies rarely use focus groups, except for the initial generation of ideas. Indeed, the inventor of focus groups, Robert Merton (1987) rejected them as sources of evidence, given the unnatural discourse of even the best-moderated group, the difficulty of hearing individuals out, and the impressionistic coding of contributions. He preferred *focused interviews*, akin to mental models interviews without the normative analysis. Whichever methods researchers use, they are likely to miss the mark unless they listen to decision-makers' perspectives, before imposing structured methods or designing communications.

Creating communications

Selecting information

Communication design begins by selecting content. The gold standard is a normative analysis, identifying the information most relevant to the choices that the communication is meant to inform. In practice, though, the content-selection process often is ad hoc, with experts intuiting 'what people ought to know' (Nickerson 1999). Poorly selected information can waste recipients' time, take the place of relevant content, or bury facts that people need to know among others that might only be nice to know. Poorly selected information can erode recipients' faith in the experts responsible for communications (and in the institutions employing them), by showing insensitivity to their informational needs ('Why are you telling me X, when I need to know Y?'). It can also undermine experts' faith in their audience, if they fail to realize that their messages have missed the mark. For example, Florig and Fischhoff (2007) found that it was impractical for many individuals to secure and store items on official lists of emergency provisions. Recipients of such advice might ask why they were being asked to do the impossible (Fischhoff, 2011).

The logic of setting information priorities is straightforward: begin with the facts that will have the greatest impact, if they are properly understood. In economics terms, that means creating a 'supply curve' for facts, ordered by their importance. That task can be formalized in 'value of information analysis' (vonWinterfeldt and Edwards 1986; Sox et al. 2007), as used by Merz et al. (1993) in setting priorities when securing informed consent for medical procedures, with carotid endarterectomy as a case study. Scraping out the main artery to the brain can reduce stroke risk, but also cause many problems, including strokes. Attempting to communicate all these risks could easily overwhelm patients. The research identified the risks that mattered most by creating a population of hypothetical patients, varying in their physical condition and health preferences, all of whom would want the procedure were there no side effects (and were money no object). The analysis then asked what percentage of these patients should decide against the surgery,

upon learning about each possible side effect. It found that only three of the many side effects (death, stroke, facial paralysis) were sufficiently likely and severe to change many decisions. Although nothing should be hidden, communications should be sure to get the few key facts across.

At times, people are not required to make a specific choice, but are just trying to understand a situation that could pose many decisions (e.g. a newly diagnosed disease, food-borne illness). The same logic of prioritization applies here as well. Communications should focus on the information that is most useful for predicting the outcomes that matter most (e.g. the critical signs of health problems, the key determinants of food safety). That information completes the *mental model* that people need to monitor their environment, generate action options, and follow discussions on the topic (Morgan et al. 2001). Here, too, building on individuals' existing knowledge allows focusing communications on critical gaps (while also demonstrating that the experts know what their audience already knows). For example, Downs et al. (2004a) found that most teens knew so much about HIV/AIDS that communications could focus on a few critical gaps, such as how risks mount through repeated exposure and how hard it is for sexual partners to self-diagnose their own disease status.

An essential part of the content of any communication is the strength of the evidence supporting it (O'Hagan et al. 2006; Politi et al. 2007). The most dangerous beliefs are those held with too great or too little confidence, leading to overly risky or overly cautious actions. Campbell (2011) shows ways to represent uncertainty graphically. Schwartz and Woloshin (2011) showed how much can be conveyed with text describing the quality of the data (e.g. the length, size, and quality of clinical trials). Funtowicz and Ravetz (1990) showed how to characterize the quality of the underlying science, including its *pedigree* (e.g. the extent to which empirical patterns are supported by theory). As an example of how an assessment of uncertainty can inform choices, a meta-analysis (Fortney 1988) concluded, with great confidence, that oral contraceptives may increase a non-smoking woman's life expectancy by up to 4 days and decrease it by up to 80 days. Moreover, the research base was so large that no conceivable study could materially change those bounds.

Formatting information

Once selected, information must be presented. Reimer and Van Nevel (1999) and Wogalter (2006) provide important pointers on research on alternative displays. They note, for example, that comprehension improves when: (1) text has a clear structure, corresponding to recipients' intuitive representation; (2) there is a clear hierarchy of information; and (3) readers receive *adjunct aids*, such as highlighting, advanced organizers (showing what to expect), and summaries.

Scientifically established design principles provide a point of departure for arranging information. These are better 'best guesses' than those informed merely by intuition. Their success in any specific application is an empirical question, though, which can be studied with standard usability testing procedures, such as seeing how long it takes users to find designated pieces of information, how often they reach the wrong information, and how likely they are to realize that (Wogalter 2006). Riley et al. (2001) developed a general method for evaluating the adequacy of communications, drawing on basic research into search patterns. Taking methylene

chloride-based paint stripper as a case study, the method begins by identifying critical information (in this case the steps that most effectively reduce exposures to the chemical and its by-products). It then evaluates product labels by seeing what risk-related information would be found by users who search in different ways. For example, a label might reveal critical information to someone who reads the first five items, but not someone who only reads the instructions or just highlighted material. Actual experience will depend on the prevalence of these search patterns (e.g. what percentage of users look at black box warnings or have instructions read to them). Unless the communication format fits users' natural search patterns, its information might be hidden in plain sight. Riley et al. found that some paint stripper products made critical, useful precautionary information accessible to any reader, while some helped only some readers (e.g. those who read warnings first), and some omit critical information altogether.

Evaluating communications

However sound their theoretical foundations, communications must be empirically evaluated (National Research Council 1989; Slovic 2001). One should no more release an untested health communication than an untested drug. Indeed, communications are part of any medical product or procedure, shaping when it is chosen, how it is used, and whether problems are noticed in time to be remedied and reported. Arguably, evidence about the effectiveness of such communications should be part of the evidence submitted when requesting approval of a product, or when conducting post-licensing surveillance of its benefits and risks in actual use.

A communication is *adequate* if it:

- ◆ Includes the information that recipients need, in order to make decisions about risks.
- ◆ Affords them access to that information, given their normal search patterns.
- ◆ Allows them to comprehend that information, with a reasonable effort.

Applying each of these three tests requires evidence. Knowing what information people need requires learning their goals, which may differ from those of the experts providing the information. Knowing whether people can find the information that is there requires observing how they search. Knowing how much they comprehend requires seeing how well they have mastered the content.

As seen in the references to this chapter, applying these tests to a publication standard is a serious undertaking, requiring professional training. However, simple versions of each test are within the reach of any communicator. The US Food and Drug Administration's *Communicating Risks and Benefits: An Evidence-Based User's Guide* (Fischhoff et al. 2011) ends each chapter with a section on how to conduct evaluations at no cost, a small cost, and a cost commensurate with the stakes riding on effective communication. Central to all forms of evaluation is listening, without presuming to know recipients' goals, beliefs, uncertainties, emotions, or modes of expression. In order to identify individuals' information needs, ask how they see the risks in the context of their lives. In order to see how easily people can access information, watch as they search for it in existing sources (e.g. online) and drafts of proposed communications (Downs et al. 2008). In order to assess a communication's comprehensibility, ask people to recall it, paraphrase it, make

inferences from it, or create scenarios using it (Bruine de Bruin et al. 2009).

These are all structured ways of conducting conversations about technical topics of mutual interest, designed to bridge some of the social distance between experts and lay people. For these methods to succeed, they also need to bridge any perceived status difference. Thus, they must be framed as testing the communications, not the recipients, in order to help experts to help the public. Almost any open-minded data collection is better than none. Thus, even a few open-ended, one-on-one interviews might catch incomprehensible or offensive material. The core presumption of risk communication should be that, if lay people have not learned facts that matter to them, the expert community must have failed to get that information across to them. Only if scientific resources have been exhausted should it be assumed that laypeople are incapable of learning the required information. The stakes riding on facilitating lay decision-making should justify that investment and humility. Amateurish, unscientific communications can be worse than nothing, by holding audience members responsible for failing to understand risks when the information was missing, inaccessible, or incomprehensible.

The science of communication can guide both *persuasive communications*, designed to influence individuals to act in ways determined by the communicator, and *non-persuasive communications*, designed to help individuals identify actions in their own best interest. The two kinds of communication converge when persuasive communicators establish that they are influencing people in ways that they would accept as being ‘for their own good’ (Thaler and Sunstein 2009). Without studying people’s goals, however, one risks imposing experts’ views on them. For example, in a study mentioned earlier, Bostrom et al. (1992) found people who rejected persuasive communications that advocated testing for radon because they wanted to avoid creating evidence that could complicate selling their homes. Fischhoff (1992) reports on the conflicting advice given to women about reducing the risk of sexual assault, reflecting differences in the goals that experts attribute to the women (and in beliefs regarding the effectiveness of self-defence strategies) (Farris and Fischhoff, 2012). Slovic and Fischhoff (1983) describe how reasonable individuals may ‘defeat’ safety measures by gaining more benefit from a product (e.g. driving faster with a car that handles better), frustrating policymakers concerned solely with safety.

Managing communication processes

In order to communicate effectively, organizations require four kinds of expertise:

1. *Subject matter specialists*, who can identify the processes that create and control risks (and benefits).
2. *Risk and decision analysts*, who can estimate the risks (and benefits) most pertinent to decision-makers (based on subject matter specialists’ knowledge).
3. *Behavioural scientists*, who can assess decision-makers’ beliefs and goals, guide the formulation of communications, and evaluate their success.
4. *Communication practitioners*, who can create communication products and manage communication channels, getting messages to audiences and obtaining feedback from them.

The work of these experts must be coordinated, so that they play appropriate roles. For example, behavioural scientists should not revise text (trying to improve its comprehensibility) without having subject matter specialists check that the content is still accurate; subject matter specialists should not slant the facts according to their pet theories of how the public needs to be alarmed or calmed. Without qualified experts, these roles will be filled by amateurs, imperilling the organization and its public.

Conclusion

Effective risk communication is essential to managing risks in socially acceptable ways. Without it, individuals are denied the best possible chances of making sound choices—before, during, and after problems arise. As a result, they may suffer avoidable injury, along with the insult of feeling that the authorities have let them down, by not creating and disseminating the information that they needed, in a timely, comprehensible way. One should no more expose individuals to an untested risk communication than to an untested medical product or procedure.

Effective risk communication focuses on the decisions that people face. Without that focus, one cannot know what information they need. Sound risk management requires not only communicating that information, but also creating it, both through risk analyses, summarizing existing research (see Chapter 7.5), and new research creating the basis for risk analyses (most other chapters in this textbook). As a result, effective risk communication cannot be just an afterthought, letting the public know what the authorities have decided. Rather, it must be central to risk management, as part of disciplined, continuing, two-way communication between decision-makers and the authorities.

This chapter has focused on measurement, rather than on general theories about how people perceive and respond to risks. That is because critical details vary across risk decisions and decision-makers. Sweeping generalizations about what ‘people do’ or ‘people think’ or ‘people want’ undermine the attention to detail that responsive risk communications require. Separate research programmes could be dedicated to communicating the science presented in many chapters in the textbook, ensuring that the public gets full value from that science. However, the methods for studying judgement and decision-making are sufficiently general and well understood that they could be applied in any domain, and for any form of information dissemination. Given a well-characterized decision or risk, it is relatively straightforward, if technically demanding, to assess lay (or expert) perceptions. If decision-makers’ risk (and benefit) perceptions have been measured well, their choices can often be roughly predicted with simple linear models (Dawes et al. 1989). More precise prediction requires more detailed understanding of the cognitive processes shaping these beliefs, as well as an understanding of the emotional, social, economic, and other factors impinging on specific decisions. Prediction may not be that important, when the public health goal is helping people to make the best choices or empowering them to change their circumstances.

Meeting the challenge of effective risk communication requires coordinating the activities of four kinds of experts: subject matter specialists, risk and decision analysts, behavioural scientists, and communication practitioners. Assembling those teams requires leadership, seeing communication as being essential to the public

health mission. The research itself is inexpensive, relative to the stakes riding on sound risk decision-making, both for individuals and for the public health organizations expected to serve them. There is no good reason for the measurement of risk perceptions and the evaluation of risk communications to use less than the readily available methods described here. There is no good reason to ignore well-established results, such as the multidimensional character of 'risk', the problems with verbal quantifiers, and the need to help people to understand how risks mount up through repeated exposure. Ad hoc communications might reflect sound intuition, but they deserve less trust than scientifically developed ones.

By definition, better risk communication should help its recipients to make better choices. It need not make the communicators' lives easier—recipients may discover bona fide disagreements with the communicators and their institutions. What it should do is avoid conflicts due to misunderstanding, increasing the light-to-heat ratio in risk management, leading to fewer but better conflicts (Fischhoff 1995).

Epidemiology and prevention of cardiovascular disease

Nathan D. Wong

Introduction to epidemiology and prevention of cardiovascular disease

Cardiovascular disease (CVD) is the leading cause of morbidity and mortality, accounting for 17.3 million deaths globally each year and this figure is expected to grow to 23.6 million by the year 2030; 80 per cent of these deaths occur in lower- and middle-income countries (Mendis et al. 2011). It is the largest contributor to non-communicable diseases (NCDs) that are now responsible for the largest share of morbidity and mortality worldwide. The incidence of CVD, including coronary heart disease, heart failure, and stroke, as well as the prevalence of key risk factors, varies greatly according to geographical region, gender, and ethnic background. Multiple longitudinal epidemiological studies have provided valuable insights into the natural history and risk factors associated with the development and prognosis of CVD. Randomized clinical trials have demonstrated the value of management of several key risk factors for both the primary and secondary prevention of CVD. This chapter discusses the epidemiology of CVD, its associated risk factors and evidence for their control, assessment of CVD risk, and the evidence behind the control of CVD risk factors for the prevention of CVD.

Definitions, incidence, and distribution

CVD comprises many conditions, including coronary heart disease, heart failure, rheumatic fever/rheumatic heart disease, stroke, and congenital heart disease. Ischaemic heart disease, consisting principally of coronary heart disease (CHD), is the predominant manifestation of CVD and is responsible for 46 per cent of deaths due to CVD in men and 38 per cent in women, followed closely by cerebrovascular disease at 34 per cent and 37 per cent, respectively (Fig. 8.1.1). While the burden of CVD was highest in Western countries during much of the twentieth century, the highest rates of CVD now occur among certain Asian and Middle Eastern regions (Fig. 8.1.2). By country, total death rates (per 100,000) from CVD, CHD, and stroke are highest in the Russian Federation for both men (1185, 659, and 308, respectively) and women (463, 221, and 158, respectively) and among the lowest in Israel for men (133, 72, and 24, respectively) and in France for women (51, 12, and 14, respectively), with intermediate rates in the United States (250, 143, and 30, respectively, in men and 124, 56, and 22, respectively, in women) (Go et al. 2013).

In the United States, the overall prevalence of CVD (including hypertension) increases dramatically from 12.8 per cent in men between the ages of 20 to 39 years to 83.0 per cent for men above 80 years old; the corresponding figures for women are 10.1 per cent and 87.1 per cent (Go et al. 2013).

Of note, however, is the substantial reduction in CVD mortality rates in the United States over the past three decades, both in men and in women, although absolute mortality from CVD in women since 1985 has exceeded that observed in men. These declines have been attributed both to improved treatments for CVD and its associated risk factors, as well as to improvements in lifestyle factors such as substantial declines in cigarette smoking, although the increasing obesity epidemic is expected to negate some of these reductions in CVD.

Myocardial infarction, angina pectoris, and sudden coronary death are the major clinical manifestations of CHD. CHD initially presents as sudden coronary death in approximately one-third of cases. Other forms of documented CHD include procedures performed as a result of documented significant atherosclerosis, such as coronary artery bypass grafting (CABG) or percutaneous coronary interventions (PCI), including angioplasty and stenting. People with documented significant disease from a coronary angiogram, echocardiogram, nuclear myocardial perfusion, magnetic resonance imaging, or computed tomography (CT) angiographic or coronary calcium scan can also designate the presence of CHD; however, because the definitions used to define significant CHD vary and these findings often do not result in hospitalization or hard CHD events, such people are not normally counted as incident or prevalent CHD, particularly for the purposes of end points in epidemiological studies or clinical trials. Non-fatal or fatal myocardial infarction or sudden coronary death are most typically included as 'hard' CHD end points, while 'total' CHD may additionally include angina requiring hospitalization as well as PCI or CABG.

CHD prevalence rates vary dramatically by age and gender in the United States. The most recent statistics from 2007 to 2010 showed that 15.4 million US adults aged 20 years and greater have CHD; this varies widely by race and gender within the United States. For example, for males, while the overall prevalence was 7.9 per cent, the prevalence in non-Hispanic white males was 8.2 per cent, in black males 6.8 per cent, and in Mexican-American males 6.7 per cent. The corresponding figures for females were 5.1 per cent overall, 4.6 per cent in non-Hispanic white females, 7.1 per cent in

Fig. 8.1.1 Proportion of deaths from cardiovascular disease (CVD) due to ischaemic heart disease, cerebrovascular disease, and other CVD causes in males (A) and females (B).

Reproduced with permission from Mendis S, Puskas P, and Norrving B (eds), *Global Atlas on Cardiovascular Disease Prevention and Control*, World Health Organization, Geneva, Switzerland, Copyright © 2011, available from http://www.who.int/cardiovascular_diseases/publications/atlas_cvd/en/.

black females, and 5.3 per cent in Mexican-American females. In the United States, there is a heart attack every 44 seconds. CHD makes up more than half of all CVD deaths in men and women under 75 years of age, with a lifetime risk of developing CHD after age 40 years, of 49 per cent for men and 32 per cent for women (Go et al. 2013).

Other important manifestations of CVD include cerebrovascular disease (including stroke and transient ischaemic attacks), heart failure, atrial fibrillation, and peripheral arterial disease, in particular. Somewhat less common but still of significance are valvular heart disease, rheumatic heart disease, and bacterial and valvular endocarditis.

Cerebrovascular disease includes stroke and transient ischaemic attacks (TIAs). Stroke prevalence in the United States ranges from less than 1 per cent in those under 40 years of age to 14 per cent in both genders in those aged 80 years and over. An estimated 6.8 million Americans aged 20 years and over have had a stroke; each year an estimated 795,000 people experience a new or recurrent stroke, with approximately 610,000 of these cases being first attacks. Of all strokes, about 87 per cent are ischaemic and 10 per cent are intracerebral haemorrhagic strokes, and 3 per cent subarachnoid haemorrhage strokes (Go et al. 2013). The self-reported prevalence of physician-diagnosed TIAs is about 2.3 per cent, translating to approximately 5 million people, but the true prevalence is likely to be greater as many with neurological symptoms consistent with TIA fail to report them to their healthcare provider. About 15 per cent of all strokes are preceded by a TIA.

While mortality rates due to total CVD, and especially CHD and stroke, have declined substantially over the past 30 years, hospitalizations due to total CVD have increased, much of this fuelled by the more than doubling in the number of hospitalizations due to heart failure between 1980 and 2010 (1,023,000 in 2010 in the United States). It is projected that this will increase by another 25 per cent by the year 2030. The prevalence of heart failure ranges

from less than 1 per cent in those under age 40 to 9 per cent of men and 12 per cent of women aged 80 years and over.

Peripheral arterial disease is highly prevalent affecting approximately 8.5 million Americans aged 40 years and over and is associated with significant morbidity and mortality; it is most common in older people over age 55 and is asymptomatic in most cases, being diagnosed by a Doppler tool measuring the ankle-brachial index (ABI), where a value of less than 0.9 is diagnostic of peripheral arterial disease. The estimated prevalence in the US population is 4.6 per cent; only about 10 per cent of those with peripheral arterial disease actually have the classic symptoms of intermittent claudication (or leg pain) (Go et al. 2013).

Estimates of the prevalence of valvular heart disease, which includes aortic, mitral, and tricuspid valve disorders, range from less than 1 per cent in those under the age of 45 years to 12–13 per cent in those aged 75 years and over. Rheumatic heart disease while uncommon in developed countries, affects more than 15 million individuals in Africa, Asia, and the Pacific, causing over 200,000 deaths annually. Infective endocarditis is relatively rare and results from formation of nonbacterial thrombotic endocarditis on the surface of a cardiac valve, bacteraemia, and adherence of the bacteria in the bloodstream; the estimated risk in the general population is as low as one case per 14 million dental procedures (Go et al. 2013).

Risk factors for cardiovascular disease

The Framingham Heart Study, the seminal epidemiological study of CVD, is a large longitudinal investigation that started in 1948 in the small town of Framingham, Massachusetts, United States. The original cohort of 5209 participants aged 30–62 years of age received biennial physical examinations, risk factor assessments, and surveillance for CVD events (Wong and Levy 2013). The

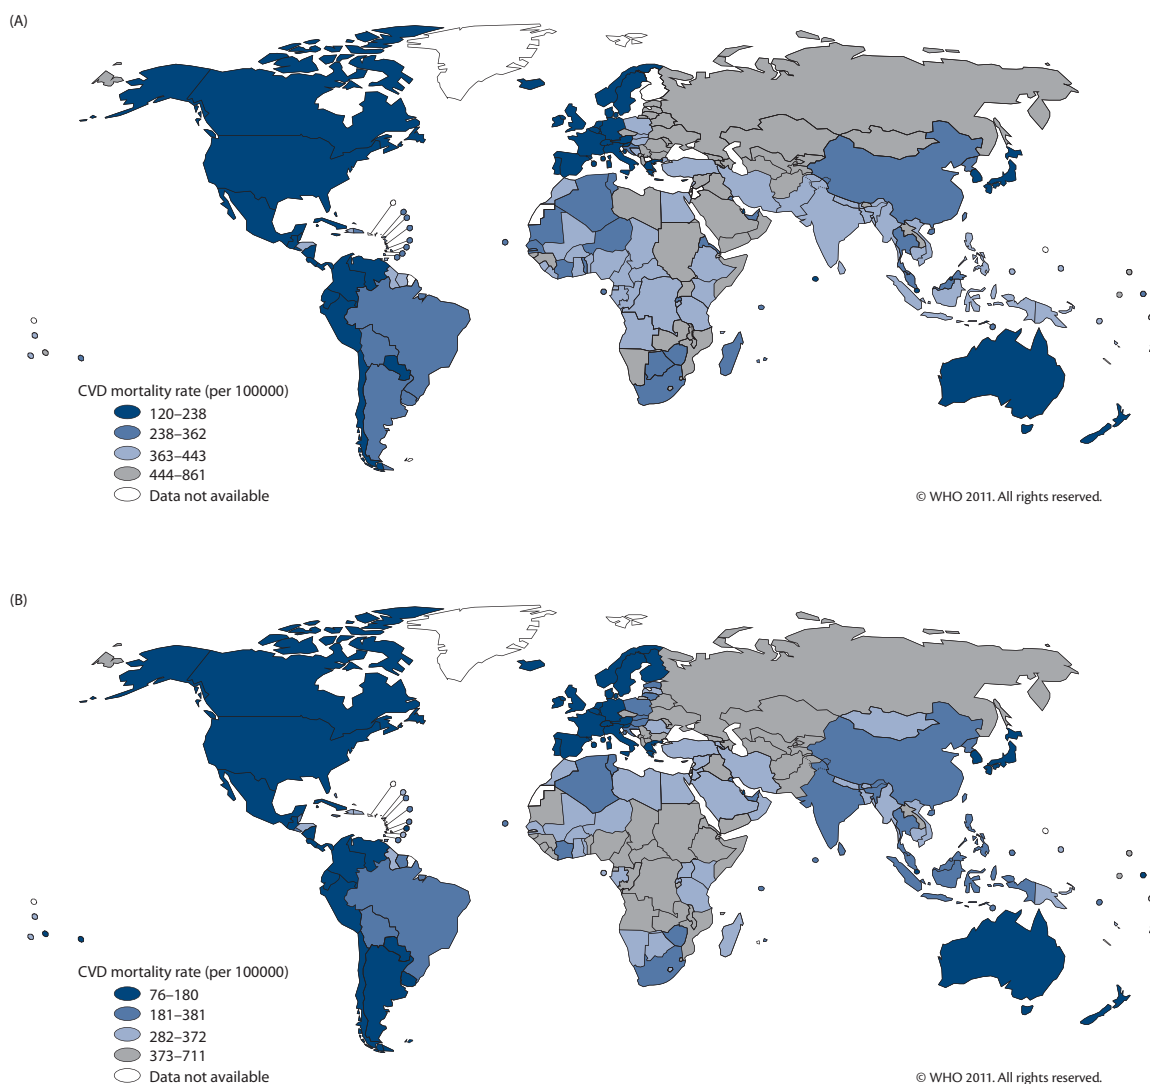

Fig. 8.1.2 Global distribution of CVD mortality rates in males (A) and females (B), age-standardized per 100,000.

Framingham study was instrumental in the original identification of many of the factors that are associated with an increased risk of CVD and, in 1961, coined for the first time the term ‘risk factors’ that is widely utilized in many different fields of medicine today (Kannel et al. 1961). The increased awareness of major risk factors for CVD initially identified by the Framingham Heart Study and by other researchers provided the impetus for important public health initiatives against smoking in the 1960s, hypertension in the 1970s, and hypercholesterolaemia in the 1980s. More recently, obesity and physical inactivity have also been recognized as key risk factors for CVD. Diabetes is also now widely regarded as a CHD risk equivalent and the importance of a clustering of major cardiometabolic risk factors, commonly referred to as the metabolic syndrome, has received significant attention from the research and clinical community (Grundy et al. 2005). Risk factors often cluster together, and the number of risk factors present and their co-occurrence are directly related to the incidence of CHD (Fig. 8.1.3). Importantly, it was the Framingham Heart Study that

first introduced the concept of multivariable or global risk assessment for coronary heart disease (see also ‘Global risk scores for cardiovascular disease risk assessment’) (Wilson et al. 1998).

Family history and genomics

A family history of premature CHD is a well-established, but unmodifiable risk factor for future CHD, and can sometimes be the crucial and single most important risk factor in predisposing an individual to early CHD (Hopkins et al. 2000; Williams et al. 2001). A large proportion of heart attacks or strokes occurring at a young age are felt to be attributable to inherited or familial predisposition. Hence, knowledge of an individual’s family history can help guide preventive efforts. A family history of premature CHD is generally defined as having a male first-degree relative experiencing a first manifestation of CHD under the age of 45, or a female first-degree relative experiencing CHD under the age of 55. The number of affected relatives with premature CHD is also felt to be an important factor, since those with one affected relative

Fig. 8.1.3 Estimated 10-year CHD risk in 55-year-old adults according to levels of various risk factors: Framingham Heart Study.
Source: data from Wilson PWF et al., Prediction of Coronary Heart Disease Using Risk Factor Categories, *Circulation*, Volume 97, pp. 1837–1847, Copyright © 2008 American Heart Association, Inc. All rights reserved.

can be shown to have a fourfold greater risk of CHD, while those with two or more affected relatives may have more than a 12-fold greater risk of CHD compared to those without any affected relatives (Hopkins et al. 2000). Moreover, it has been shown that 35 per cent of all early CHD occurs in just 3.2 per cent of families, all of whom have a strong positive family history of CHD. Familial hypercholesterolaemia (FH) is an autosomal dominant condition associated with very high levels of total and low-density lipoprotein cholesterol (LDL-C) (total cholesterol levels exceeding 500 are commonly reported) where individuals inherit from one or both parents (homozygous) a defective LDL-C receptor gene. Affected individuals have been known to have heart attacks and die by the age of 20 and FH is among the most widely studied genetic conditions responsible for CHD. Other genetic defects responsible for hypertension, obesity, diabetes, and other major cardiovascular risk factors have also been identified and are the subject of major investigations (Williams et al. 2001).

In recent years, with the ability to sequence the entire human genome, key single-nucleotide polymorphisms (SNPs) have been identified and linked to the likelihood of CHD, although with a much higher threshold required to confirm a statistically significant relationship ($p = 10^{-8}$) (Schunkert et al. 2011). One region that has received significant attention is 9p21 because of its strong association with CHD (Palomaki et al. 2010). However, the utility of such SNPs in improving the ability to predict CHD over traditional risk factors is only modest and current guidelines have not recommended genomic screening due to the thus far limited demonstrated clinical utility.

Diabetes and metabolic syndrome

Diabetes mellitus is a major risk factor for CVD, and is associated with a greater risk for CHD, stroke, chronic kidney disease, and

peripheral vascular disease (Kaseta et al. 2005). There are wide variations in prevalence according to gender and ethnicity. In 2009–2010, among US adults, the prevalence of physician-diagnosed diabetes mellitus was lowest in white people (6.2 per cent in females and 7.7 per cent in males) and highest in non-Hispanic black people (15.4 per cent in females and 13.5 per cent in males).

More than three-quarters of those with diabetes die of cardiovascular complications, most notably myocardial infarction and stroke. Given this point, the National Cholesterol Education Program designated diabetes as a CHD risk equivalent (Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults 2001) because the risk of CHD in those with diabetes without known heart disease had been shown to be similar to recurrent CHD events in those with CHD (but without known diabetes), although more recent studies are showing that this is not always the case. Most population-based studies have shown about a twofold greater risk of CHD in men with diabetes as compared to men without diabetes, but in women, the corresponding figure is a three- to seven-fold greater risk of CHD.

Diabetes is typically diagnosed by a glycated haemoglobin (HbA1c) level of 6.5 per cent or greater, fasting glucose of 126 mg/dL (7 mmol/L) or above, or glucose level of at least 200 mg/dL (11.1 mmol/L) from the non-fasting state or after a 2-hour post-load glucose challenge test (American Diabetes Association 2013). Pre-diabetes is diagnosed by a fasting glucose of 100–125 mg/dL or casual glucose of 140–199 mg/dL.

Clinical trial evidence to show whether intensive glycaemic control in people with diabetes lowers CVD event rates has shown mixed results. The United Kingdom Prospective Diabetes Study (UKPDS) originally showed a borderline, non-significant ($p = 0.052$) 16 per cent reduction in risk of myocardial infarction among those with newly diagnosed type 2 diabetes who were

treated with intensive glucose lowering therapy, but the 10-year post-interventional follow-up of this study, which was recently published, showed that these benefits continued with a 15 per cent significant ($p = 0.01$) reduction in risk of myocardial infarction (Holman et al. 2008). A similar, extended post-interventional follow-up of the Diabetes Control and Complications Trial of Type 1 diabetes, which did not initially show a significant reduction in CVD events at the end of the randomized trial, showed years later a continued effect of the original intensive glucose-lowering treatment, with a 42 per cent reduction in the risk of any cardiovascular event (Nathan et al. 2005). Such a continued post-trial effect of the randomized glycaemic therapy has been termed a 'glycaemic legacy' effect. More recently, however, three important randomized clinical trials (the Action to Control Cardiovascular Risk in Diabetes (ACCORD), ADVANCE, and the Veterans Affairs Diabetes Trial (VADT)) failed to show that intensive glucose lowering to a HbA1c range of 6–6.5 per cent significantly reduced CVD event rates, as compared to more standard maintenance of the HbA1c in the 7–9 per cent range. In fact, those randomized to the intensive therapy group in ACCORD actually had a higher rate of CVD mortality (Action to Control Cardiovascular Risk in Diabetes Study Group et al. 2008), although this increased risk was restricted to those with prior macrovascular disease and where there was unsuccessful lowering of the glucose as a result of the intensive therapy. Those with less complicated diabetes (e.g. patients who were more recently diagnosed and without prior macrovascular disease) actually showed a benefit in the primary end point. Moreover, an important lipid substudy of ACCORD tested the efficacy of adding the fibric acid derivative fenofibrate or placebo to ongoing statin therapy and found no benefit in terms of reducing CVD event rates (although there was a benefit seen in the subgroup with high triglycerides and low high-density lipoprotein cholesterol (HDL-C)) (ACCORD Study Group 2010a). In addition, in the blood pressure substudy of ACCORD, intensive blood pressure therapy to achieve a systolic blood pressure less than 120 mmHg, as compared with less than 140 mmHg, was also found to provide no significant benefit in terms of CVD risk reduction, although there was a significant benefit in stroke reduction (ACCORD Study Group 2010b).

Of particular interest in the past decade has been the designation of metabolic syndrome, referring to a constellation of cardiometabolic risk factors that are associated with a greater risk of developing future diabetes and CVD. This clinical condition has been useful for the purposes of defining those with multiple risk factors which place them at greater CVD risk, and who may benefit from a more intensified, unified approach at risk factor modification. Studies have documented that 30–40 per cent of adults have metabolic syndrome in the United States, with even higher prevalence rates in some countries such as in the Middle East. Certain definitions of the metabolic syndrome place insulin resistance or abdominal obesity as the necessary condition, with additional conditions including elevated blood pressure, low HDL-C, elevated triglycerides, and impaired fasting glucose making up the definition. The American Heart Association (AHA)/National Heart Lung and Blood Institute definition (Grundey et al. 2005) requires the presence of at least three of the following five criteria: abdominal obesity defined by a waist circumference greater than 35 inches (89 cm) in women or greater than 45 inches (115 cm) in men; HDL-C less than 40 mg/dL in men or less than 50 mg/dL

in women, fasting triglycerides of 150 mg/dL or above; elevated blood pressure of 130 mmHg systolic or above, or 85 mmHg diastolic or above, or on hypertensive therapy; or impaired fasting glucose defined as at least 100 mg/dL (5.6 mmol/L) or on hypoglycaemic therapy. It is important to recognize that other definitions exist, such as that from the International Diabetes Federation which requires the presence of abdominal obesity as measured by lower waist circumference cut-off points in European Caucasians (> 94 cm in men and > 80 cm in women), and among most Asian groups and those of Central and South American ancestry (where > 80 cm in women and > 90 cm in men define increased waist circumference) (Alberti et al. 2005).

Numerous studies have shown an increased risk of future CVD events in people with the metabolic syndrome. Among adults in the United States (Malik et al. 2004), a stepwise increase in risk for CHD, CVD, and total mortality has been shown relating to the presence of metabolic syndrome alone, metabolic syndrome with diabetes or pre-existing CVD, and metabolic syndrome with both CVD and diabetes (Fig. 8.1.4).

Hypertension

Elevated blood pressure, and particularly systolic blood pressure, is strongly and positively related to the risk of future CHD and stroke. Hypertension is currently defined as a systolic blood pressure of 140 mmHg or higher, diastolic blood pressure of 90 mmHg or higher (or on pharmacological treatment to lower blood pressure). Elevated blood pressure at levels of 140–159 mmHg systolic or 90–99 mmHg diastolic is defined as stage 1 hypertension, and levels of 160 mmHg or higher systolic or 100 mmHg or higher diastolic is defined as stage 2 hypertension. In 2010, the prevalence of hypertension in US adults aged 20 years and over was 33.6 per cent in men and 32.2 per cent in women, ranging from 18.7 per cent among Asians to 47 per cent in Non-Hispanic black females (Go et al. 2013). Prevalence ranges from under 10 per cent in those younger than 35 years of age and progressively increases with age to more than 70 per cent in those aged 75 years and over with higher prevalences in men before age 55, but higher prevalences in women after age 65 (reaching 80 per cent among those aged 75 years and over). Of note, isolated diastolic hypertension (systolic blood pressure of < 140 mmHg but diastolic blood pressure of 90 mmHg or higher) is the most common form of hypertension under age 50, while isolated systolic hypertension (systolic blood pressure of 140 mmHg or higher, but diastolic blood pressure < 90 mmHg) predominates over the age of 60 years (Franklin et al. 2001). The Seventh Joint National Committee on Prevention, Detection, Evaluation and Treatment of High Blood Pressure (Chobanian et al. 2003) also defines those with a level of blood pressure of 120–139 mmHg systolic or 80–89 mmHg diastolic as 'pre-hypertensive' because of the greater future risk for these people to develop hypertension (one-sixth to one-third of such people will become clinically hypertensive in the next 4 years). Approximately one-third of US adults are pre-hypertensive. Blood pressure is not considered normal unless it is less than 120 mmHg systolic and < 80 mmHg diastolic. For every blood pressure increase of 20/10 mmHg (systolic/diastolic) above 115/75 mmHg, the risk of death from CHD, stroke or CVD doubles (Lewington et al. 2002). While there have been major improvements in the treatment of hypertension, only about one-third of adult patients with hypertension are adequately controlled. This varies substantially

Fig. 8.1.4 Relative risks for mortality from coronary heart disease, cardiovascular disease, and all causes in United States adults associated with the presence of metabolic syndrome with and without diabetes: NHANES II: 1976–1980 follow-up study (mean 13 years follow-up).

Reproduced from Malik S. et al., Impact of the metabolic syndrome on mortality from coronary heart disease, cardiovascular disease, and all causes in United States Adults, *Circulation*, Volume 110, Issue 10, pp. 1239–1244, Copyright © 2004 American Heart Association, Inc. by ethnicity and gender, ranging from a low of 38 per cent in Mexican-American males to as high as 56.8 per cent among white females (Go et al. 2013).

Numerous clinical trials have shown that lowering blood pressure substantially decreases the risk of future cardiovascular events, stroke, and end-stage renal disease. A large meta-analysis of active treatment (with initial low dose diuretic, beta blocker, angiotensin-converting enzyme (ACE) inhibitor or calcium antagonist) compared to placebo showed significant reductions in the risk for heart failure (36 per cent), stroke (33 per cent), CHD (16 per cent), CVD death (15 per cent), overall CVD (25 per cent), and total mortality (12 per cent) (Elliott 2005).

Dyslipidaemia

Increased levels of total and LDL-C have long been recognized as major risk factors for CHD. A direct curvilinear relation exists between total and LDL-C and the risk of CHD. For example, compared to those with total cholesterol levels of 200 mg/dL, those with levels of 240 mg/dL are at approximately twofold greater risk, while those with levels of 300 mg/dL have a fourfold increased risk. A population optimal LDL-C level has been designated as less than 100 mg/dL with levels of 130 mg/dL, 160 mg/dL, or 190 mg/dL often considered the thresholds for beginning lipid-lowering therapy in those at high, intermediate, or low CHD risk, respectively (Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol 2001). However, there is significant overlap in total or LDL-C levels between those who experience CHD events versus those who do not and approximately one-third of heart attacks occur in people with 'normal' levels of total cholesterol below 200 mg/dL. Importantly, a low level of HDL-C (typically defined as < 40 mg/dL in men and < 50 mg/dL in women), regardless of level of total cholesterol, is strongly associated with an increased risk of CHD (Castelli et al. 1986). For example, across levels of total cholesterol from less than 200 mg/dL to 260 mg/dL or above, the 14-year incidence of CHD varies only from 11.2 to 12.5 per cent, whereas when HDL-C is less than 60 mg/dL, these rates are 3.7 to 3.8 per cent respectively.

Other lipid abnormalities include elevated serum triglyceride levels (the normal level is considered to be < 150 mg/dL), small particle size LDL-C (known as small dense LDL-C) and elevated lipoprotein (a) levels. There has also been recent interest in non-HDL-C since it captures all the atherogenic apolipoprotein B-containing lipoproteins and does not require, unlike LDL-C, measurements to be made after fasting. Several epidemiological studies have demonstrated a stronger relationship of non-HDL-C compared to LDL-C with incidence of CHD.

Table 8.1.1 shows the prevalence of elevated total and LDL-C and low HDL-C levels among US adults aged 20 years and over in 2010 (Go et al. 2013).

Numerous primary and secondary prevention clinical trials have documented the efficacy of lowering LDL-C, particularly with HMG-CoA reductase inhibitor drugs ('statins'), which can lead to approximately 25–35 per cent reductions in CHD and CVD incidence, where the lower the LDL-C achieved, the lower were the event rates (Rosensen 2004). These trials also showed no threshold level of LDL-C reductions where the CVD event rates begin to flatten. A large meta-analysis of 14 statin trials comprising 90,056 subjects showed that over a 5-year treatment period, every mmol/L reduction (approximately 40 mg/dL) in LDL-C achieved, was associated with reductions in all-cause mortality of 12 per cent, coronary mortality of 18 per cent, myocardial infarction and CHD death of 23 per cent, stroke incidence of 17 per cent, all major vascular events of 21 per cent, and with no difference (relative risk 1.00) in cancer incidence (Baigent et al. 2005). Importantly, several trials have shown the additional benefit of reducing the LDL-C, with high-dose statin therapy, to levels below 100 mg/dL. The largest of these, the Treat to New Targets (TNT) study showed that the achieved LDL-C of 77 mg/dL with high dosage atorvastatin therapy, when compared to achieved LDL-C of 101 mg/dL with low-dose atorvastatin therapy, resulted in an additional 22 per cent reduction in major cardiovascular events (LaRosa 2005).

Given that most randomized clinical trials of LDL-C lowering have demonstrated no more than 40 per cent reductions in CVD incidence, addressing the remaining 'residual' risk has been of

Table 8.1.1 Prevalence of elevated total and LDL-C and low HDL-C by gender and ethnicity, US adults aged 20 years and over: National Health and Nutrition Examination Survey 2010

Population	Total cholesterol \geq 200 mg/dL	Total cholesterol \geq 240 mg/dL	LDL-C \geq 130 mg/dL	HDL-C $<$ 40 mg/dL
All	43.4%	13.8%	31.1%	21.8%
Males	41.3%	12.7%	31.9%	31.8%
Females	44.9%	14.7%	30.0%	12.3%
White males	40.5%	12.3%	30.1%	33.1%
White females	45.8%	15.6%	29.3%	12.4%
Black males	38.6%	10.8%	33.1%	20.3%
Black females	40.7%	11.7%	31.2%	10.2%
Mexican-American males	48.1%	15.2%	39.9%	34.2%
Mexican-American females	44.7%	13.5%	30.4%	15.1%

great interest. One factor that has been specifically investigated has been whether the raising of HDL-C levels will provide further benefit in reducing CVD events beyond that afforded by LDL-C lowering, given the strong protective effect of increased HDL-C levels suggested by observational studies. The AIM-HIGH Trial (AIM-HIGH Investigators et al. 2011) was designed to be a rigorous test of the HDL hypothesis, randomizing 3414 men and women with a prior CVD event and low HDL-C, and who had well-controlled LDL-C levels averaging 74 mg/dL on a statin, to extended-release niacin or placebo. LDL-C levels were kept similar between the groups, and the on-treatment HDL-C level averaged 5 mg/dL higher in those on niacin. However, the trial was discontinued early due to futility, with no significant reduction in CVD events observed (hazard ratio = 1.02, $p = 0.79$). The failure of this trial, as well as that of a second much larger niacin trial, HPS2-Thrive and one involving a novel cholesterol ester transferase protein (CETP) inhibitor, dalcetrapib, have raised significant questions as to the benefit of raising HDL-C levels, particularly in patients who are already well-controlled on statins. Additionally, the use of fibrate therapy to address the residual risk associated with low HDL-C and elevated triglycerides, while initially showing benefit in the HDL Intervention Trial (HIT) among veterans with known CHD, has not been shown to provide added benefit over the background of statin therapy in the recent ACCORD Lipid Trial among people with diabetes (ACCORD Study Group 2010a).

Cigarette smoking

Tobacco smoking is among the leading preventable causes of death globally (see also Chapter 9.1). Numerous studies have linked tobacco use to the incidence of, and mortality from, CVD, with approximately half a million deaths annually in the United States being attributed to tobacco use. Further, environmental tobacco smoke ('second-hand smoke') is responsible for approximately 40,000 deaths from heart disease annually in the United States. Cigarette smokers are 2 to 4 times more likely to develop CHD than non-smokers. Also, their risk of stroke is doubled and risk for peripheral vascular disease is more than ten times higher

than that of non-smokers (Luepker and Lando 2005). The most recent data among US adults in 2010 show an overall prevalence of smoking of 19.0 per cent, with a wide variation by ethnic/gender groups, ranging from 5.5 per cent in Asian females to 24.6 per cent in American Indian/Alaska Native men (Go et al. 2013).

Obesity and physical inactivity

Recent estimates showed that two-thirds of US adults are overweight or obese (body mass index of 25 kg/m² or higher), with 30 per cent being obese (body mass index of 30 kg/m² or higher). Since the 1960s, there has been a dramatic nearly three-fold increase in obesity prevalence among men from 10.7 per cent to 34.4 per cent and more than a twofold increase in women from 15.7 per cent to 36.1 per cent. Moreover 18.8 per cent of children aged 6–11 and 18.2 per cent aged 12–17 are defined to be obese based on latest survey data from 2007 to 2010. Further recent estimates from 2007–2010 showed that barely a third of the US adult population (44.2 per cent of men and 36.2 per cent of women; and only one-third of African American women) met nationally recommended amounts of physical activity (150 minutes of moderate, or 90 minutes of vigorous activity or an equivalent combination per week) (Go et al. 2013).

Obesity has been shown by numerous studies to be associated with an approximate 1.5- to twofold increase in risk of death from CHD, with the increase in risk beginning below the 25 kg/m² cut-off point for overweight. Numerous studies also show approximately 20–40 per cent lower risks of mortality and cardiovascular events associated with increased levels of physical activity or measured fitness. Several cardiovascular risk factors are linked to obesity, including hypertension, dyslipidaemia (including low HDL-C levels), type 2 diabetes, obstructive sleep apnoea, and hyperinsulinaemia. Increases in physical fitness have also been shown to be linked to increases in HDL-C levels and reductions in systolic and diastolic blood pressure, insulin resistance, and glucose intolerance. Abdominal obesity, most commonly indicated by a waist circumference of greater than 40 inches (102 cm) in men or greater than 35 inches (89 cm) in women, is a major component of the metabolic syndrome. Studies demonstrate that weight

loss can substantially improve many cardiometabolic risk factors (McCowen and Blackburn 2005).

The National Institutes of Health's Obesity Educational Initiative provides guidelines on the identification, evaluation, and treatment of overweight and obese adults. Assessment includes measurement of body mass index, waist circumference, as well as other accompanying risk factors. Moderate hypocaloric diets of 1000–1200 kcal per day are generally recommended to provide moderate, sustained weight loss. Incorporating diet and exercise together has been shown to result in longer-term success in weight control (National Institutes of Health 1998). More recent guidelines for obesity management from the ACC/AHA have also been published, recommending regular assessment of body mass index, and in those who are overweight, waist circumference. It is emphasized that even moderate weight loss of 3–5 per cent of body weight can result in important reductions in cardiometabolic risk factors (Jensen et al. 2014). Reduced caloric intake, involving 1200–1500 kcal/d for women and 1500–1800 kcal/d for men is recommended for those who would benefit from weight loss. They also point out the importance of high intensity weight loss interventions (ideally at least 14 sessions over a 6 month period) with a lifestyle interventionist to maximize potential for weight loss.

Measures of cardiovascular health and CVD risk

In recent years, the AHA (Go et al. 2013) has promoted a goal to improve the cardiovascular health of all Americans by 20 per cent while reducing mortality from heart disease and stroke by 20 per cent by the year 2020. These goals introduce the concept of promoting cardiovascular health which is more positive and motivating than the concept of preventing *cardiovascular disease*, and have focused on examining the proportion of individuals (and the relation to CVD risk) who achieve one or more 'ideal levels' based on the following seven metrics (also known as AHA's Life's Simple Seven™): (1) cigarette smoking (non-smoking is ideal); (2) physical activity (150 minutes or more moderate

intensity or equivalent exercise per week is ideal); (3) body mass index ($< 25 \text{ kg/m}^2$ is ideal); (4) healthy diet (achieving at least four of five key dietary components focusing on fruit/vegetable, fish, fibre, and sodium intake and sweetened beverage intake); (5) cholesterol ($< 200 \text{ mg/dL}$ ideal in adults, $< 170 \text{ mg/dL}$ in children); (6) blood pressure ($< 120/80 \text{ mmHg}$ is ideal); and (7) fasting plasma glucose ($< 100 \text{ mg/dL}$ is ideal). Fewer than 20 per cent of adults and only about 40 per cent of children meet five or more of these criteria for ideal cardiovascular health and fewer than 1 per cent of adults are at ideal levels of all seven metrics of cardiovascular health. Moreover, CVD incidence varies more than tenfold according to the number of cardiovascular health behaviours and factors that are present (Folsom et al. 2011) (Fig. 8.1.5).

Risk factors for stroke

Important risk factors for stroke include elevated blood pressure, diabetes mellitus, disorders of heart rhythm, low HDL-C, cigarette smoking, family history, and chronic kidney disease (Go et al. 2013). Elevated blood pressure is the most important risk factor for both ischaemic stroke and intracranial haemorrhage, with about 77 per cent of those with a first stroke having a blood pressure of 140/90 mmHg or higher. The Framingham Heart Study demonstrated the importance of mid-life antecedent hypertension as well as systolic hypertension as important predictors of stroke (Romero and Wolf 2013). Even pre-hypertension is associated with incident stroke. Randomized clinical trials consistently show the efficacy of blood pressure control for prevention of stroke. Diabetes is also a strong predictor of stroke, although mainly before 55 years of age in black people and before 65 years of age in white people. Atrial fibrillation is another powerful risk factor for stroke, independently increasing risk approximately fivefold at all ages, with nearly one-quarter of strokes attributable to atrial fibrillation in the ninth decade of life. While elevated total cholesterol levels are not strongly predictive of stroke, some studies have found low HDL-C levels to predict risk, but clinical trials of statin therapy consistently show

Fig. 8.1.5 Incidence of CVD according to the number of ideal health behaviours and health factors.

benefits of such therapy for preventing stroke. Prospective studies have also shown moderate to vigorous physical activity to be associated with an overall 35 per cent reduction in risk of ischaemic stroke compared with no physical activity. A family history of parental ischaemic stroke before the age of 65 has also been shown to be associated with a three-fold increase in ischaemic stroke in offspring, even after adjustment for other risk factors. Finally, increased levels of creatinine and reduced glomerular filtration rate have been shown to predict future stroke and symptoms (Go et al. 2013).

Risk factors for heart failure

Hypertension is among the most prominent of risk factors for heart failure, followed by a preceding myocardial infarction, elevated B-type natriuretic peptide levels, and urinary albumin-to-creatinine ratio (Go et al. 2013). In the Physicians Health Study, the lifestyle risk of heart failure was greater in those with hypertension and less in those with healthy lifestyle factors, including normal weight, not smoking, regular exercise, moderate alcohol intake, consumption of breakfast cereals, fruits, and vegetables (Djousse et al. 2009). The Framingham Heart Study was key in demonstrating the poor prognosis associated with heart failure in the community, with one of two individuals dying within 5 years of diagnosis and the strong association of hypertension conferring nearly an eightfold risk in men and fourfold risk in women for developing heart failure. They also documented other predictors of new onset heart failure, including elevated plasma natriuretic peptide levels, asymptomatic left ventricular systolic dysfunction, and increased left ventricular diastolic dimension (Mahmood and Wang 2013).

Risk factors for peripheral arterial disease

Peripheral arterial disease shares many of the same risk factors that coronary heart disease does, although diabetes and cigarette smoking are stronger risk factors for peripheral arterial disease than for coronary heart disease with odds ratios in the range of 3–4. Another study showed hypertension, diabetes, chronic kidney disease, and smoking were associated with incident peripheral arterial disease. Pooled data from 11 studies showed that peripheral arterial disease, defined by an ABI of less than 0.9, is an independent risk factor for all-cause mortality (relative risk 1.6, 95 per cent confidence interval (CI) = 1.3–2.0) as well as cardiovascular mortality (relative risk 2.0, 95 per cent CI = 1.5–2.6) (Go et al. 2013).

Cardiovascular disease risk assessment

Global risk scores for cardiovascular disease risk assessment

In order to understand an individual's risk of CVD or CHD, it is important to understand an individual's 'global risk' of developing the condition. Most typically, this involves determination of the future risk of developing CHD in the next 10 years. This can be done by various 'risk assessment' algorithms. Most commonly used for this purpose are the Framingham Risk Algorithms that are recommended to assess an individual's 10-year risk of CHD (Kaseta and Sowers 2005) for the purposes of appropriate stratification for

risk factor management, especially for the initiation or intensification of lipid management. From knowing an individual's age, gender, systolic blood pressure (and treatment status), current smoking status, total cholesterol, and HDL-C, for which each factor is assigned a certain number of points according to its presence (and degree) or absence, a total score is obtained which corresponds to a probability of suffering a hard CHD event in the next 10 years based on Framingham follow-up data. If the projected 10-year risk of CHD is less than 10 per cent, the individual is generally considered to be at low risk of CHD, 10–20 per cent intermediate risk, and if greater than 20 per cent is judged to be at high risk, and in fact, a CHD risk-equivalent (a condition or combination of risk factors conferring a future risk or prognosis similar to that of diagnosed CHD). Use of these algorithms have been recommended for those with at least two major risk factors out of the following: family history of premature CHD (< 45 years in male or < 55 years in female first-degree relative), low HDL-C, hypertension, cigarette smoking, and advanced age (male 55 years or older or female 65 years or older). Those with fewer than two risk factors are felt to be generally at lower risk where treatment would not typically be warranted. Those with diabetes, CHD, or other atherosclerotic disease would also be designated at high risk for aggressive treatment, so such a calculation has not been recommended for such individuals (Expert Panel on Detection, Evaluation and Treatment of High Blood Cholesterol 2001).

There is, however, great heterogeneity in the end point predicted by various risk scores. For example, the 10-year CHD risk score recommended by the Third Adult Treatment Panel of the National Cholesterol Education Program (Expert Panel on Detection, Evaluation and Treatment of High Blood Cholesterol 2001) includes only hard CHD (myocardial infarction and CHD death) as its end point, thus does not include other forms of CHD (such as angina or revascularization) as well as other forms of CVD such as stroke, heart failure, and peripheral arterial disease, which are also important CVD manifestations of concern which should be included in such risk scores. Other algorithms such as the European SCORE or German PROCAMM risk scores are utilized mainly outside the United States. More recently, algorithms for total CVD risk from Framingham have been developed, which are more global as they incorporate the combined risk for CHD, stroke, heart failure, and peripheral arterial disease (D'Agostino et al. 2008). Most recently, the American College of Cardiology (ACC) and American Heart Association (AHA) released new guidelines for cardiovascular risk assessment which call for the use of a pooled cohort risk score (Goff et al. 2013). These new risk scores are based on 4 major US population-based cohort studies comprising over 25,000 black and white adults with at least 10 years of follow-up for atherosclerotic cardiovascular disease (ASCVD) events. The risk calculator provides both 10-year and lifetime risk estimates for ASCVD consisting of nonfatal myocardial infarction, CHD death, and stroke (<http://tools.cardiosource.org/ASCVD-Risk-Estimator/>).

In those where a global risk estimate is obtained, depending on the risk status, the appropriate intensity of treatment for given risk factors is considered. For instance, if an individual is found to be at high risk or to have a CHD risk equivalent, treatment for dyslipidaemia would be recommended to reduce the LDL-C level to less than 100 mg/dL. If at intermediate risk or low risk, however, these goals would be less than 130 mg/dL and less than 160 mg/dL, respectively.

While estimation of global risk as described earlier is recommended, it may be best considered a starting point in risk assessment. The presence of other risk factors not included in the risk algorithms, such as abdominal obesity, elevated triglycerides (if severe enough), impaired fasting glucose, or a strong positive premature family history, if present, however, could be used by the clinician to stratify an individual's risk or required intensity of treatment upward. Others have also recommended novel risk factors, such as C-reactive protein, a measure of systemic inflammation, or the presence of subclinical atherosclerosis, such as coronary artery calcium or carotid intimal media thicknesses, to aid in risk stratification. If these are present to a significant degree, they are being suggested as indicators for stratifying an individual's required intensity of treatment upward. The most recent American College of Cardiology/American Heart Association risk assessment guideline notes that when the treatment decision is uncertain, evaluation of premature family history of CHD, hs-C-reactive protein, ankle brachial index, or coronary calcium scoring may be considered for further risk stratification (Goff et al. 2013).

Inflammatory measures for cardiovascular disease risk

High levels of inflammatory markers, including high-sensitivity C-reactive protein (hs-CRP), a marker of systemic inflammation, as well as lipoprotein phospholipase associated A2 (LpPla2), a measure of vascular inflammation, have been shown in numerous studies to be independently related to the risk of future cardiovascular events. Interleukin-6, other interleukins, myeloperoxidase, and tumour necrosis factor-alpha (TNF-alpha) also have inflammatory activity and have been shown to be associated with cardiovascular events in some studies, as have other biomarkers such as brain natriuretic peptide (BNP) and troponin levels. Levels of C-reactive protein exceeding 3 mg/L have been designated to be associated with increased CVD risk, levels in the range of 1–3 mg/L with intermediate risk, and low risk levels have been designated as less than 1 mg/L (Pearson et al. 2003). Modest recommendations have been provided for the measurement of hs-CRP in older adults (men \geq 50 years or women \geq 60 years) with LDL-C less than 130 mg/dL (class IIa) or in those below these ages who are at intermediate risk (class IIb), for the purposes of guiding the initiation or intensification of therapy. A similar class IIb recommendation is given for the measurement of LpPla2 in asymptomatic intermediate risk adults. There are no recommendations for the measurement of other inflammatory markers or biomarkers for the assessment of CVD risk in asymptomatic adults, however (Greenland et al. 2010).

Subclinical cardiovascular disease assessment

The ability to image or directly measure the atherosclerotic burden has been of great interest but whether these measures provide added value over less expensive and easier traditional office-based risk factor measures (including global risk assessment scores) has been an important question in cardiovascular epidemiology and prevention over the past 15 years (Greenland et al. 2010). Such measures must have a high level of sensitivity and specificity for detection of the disease, must be reproducible and cost-effective, and should provide added clinical utility over current office-based risk assessment.

Increased carotid intima medial thickness (CIMT) as measured from carotid B-mode ultrasound, has been shown to be

related to the risk of future CVD events from numerous prospective epidemiological studies over the past 25 years, including the Atherosclerosis Risk in Communities (ARIC), Cardiovascular Health Study (CHS), and the Multiethnic Study of Atherosclerosis (MESA). CIMT has also been used as a surrogate end point in numerous clinical trials involving lipid-lowering and other interventions. Moreover, the presence of carotid plaques provides additional information and together with CIMT measurements have modest clinical utility for reclassification of risk in asymptomatic intermediate risk adults. Individuals with CIMT levels of 1 mm or higher or in the highest quartile for age-specific values are generally considered to be at increased risk. While persons at intermediate risk were previously given a class IIa recommendation for the measurement of CIMT (Greenland et al. 2010), more recent guidelines no longer recommend CIMT measurement for risk assessment (Goff et al. 2013).

ABI measured from ankle and arm blood pressures utilizing a Doppler, provides for an assessment of peripheral arterial disease, which is diagnosed to be present when the ABI is less than 0.9. A low ABI has also been shown to be related to increased total and CVD mortality in numerous observational studies. However, as the prevalence of a low ABI tends to be very low until after the age of 60 years, it is therefore most useful as a screening tool for peripheral arterial disease in older people. It is also a class IIa recommendation for assessment in intermediate risk individuals (Greenland et al. 2010).

Measures of coronary artery calcium (CAC) as assessed by CT, have been shown in numerous prospective studies, to be associated with the future risk of CHD and CVD events, independent of standard risk factors (Detrano et al. 2008). CAC measures also provide incremental predictive value and added reclassification of risk over global risk assessment for the prediction of cardiovascular events. In the MESA study, it has been shown to provide greater incremental risk prediction among intermediate risk individuals (from C-statistic improvement) than any other major biomarker or subclinical disease screening test (Yeboah et al. 2012). CAC testing also receives a class IIa recommendation for assessment of risk in asymptomatic subjects at intermediate risk (Greenland et al. 2010).

There are also numerous other tests which have varying levels of evidence relating them to CVD event risk. These include assessments of endothelial function, pulse wave velocity, brachial artery reactivity, and imaging of soft plaque such as by CT coronary angiography. Most of these other tests, however, do not have the quantity, strength, or consistency of evidence that CIMT, ABI, or CAC assessment do, and hence there is not the same level of consensus for recommending their use for the screening of asymptomatic adults (Greenland et al. 2010).

Preventive strategies for cardiovascular disease risk reduction

Cardiovascular epidemiology and disease prevention encompasses an extensive field investigating the distribution and variation of CVD conditions, most notably coronary heart disease and stroke, their risk factor determinants, and strategies at the population and individual level aimed at preventing the development or recurrence of CVD. Epidemiological approaches to studying CVD provide us with the tools for preventive efforts at the individual and population level. *Primordial prevention* is

aimed at prevention of the risk factors for CVD, such as efforts aimed to prevent hypertension, obesity, or dyslipidaemia. *Primary prevention*, which focuses on the modification of these and other known risk factors, is aimed at preventing the clinical manifestations of CVD, such as myocardial infarction and stroke. *Secondary prevention* focuses on those who already have manifestations of disease, but where aggressive control of risk factors can have a major impact in preventing recurrences of disease. Concerted efforts between governmental agencies, the community, and the private sector are required to best address the continuing epidemic of CVD.

Preventive strategies can be considered using the 'ABCDE' approach addressing aspirin/antiplatelet therapy (A), blood pressure and hypertension (B), cholesterol and dyslipidaemia (C), diet and nutrition (D), and exercise and physical activity (E). For secondary prevention among people with pre-existing CVD, guidelines have been published by the AHA/American College of Cardiology (Smith et al. 2011).

Aspirin and antiplatelet therapy

Aspirin prophylaxis (81–162 mg/day) has been recommended for people at intermediate risk, for the prevention of CHD in men and prevention of stroke in women, including those with diabetes or metabolic syndrome (Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults 2001; Grundy et al. 2005). Additionally, among those with pre-existing CVD, aspirin is recommended in combination with clopidogrel due to the added benefit in prevention of secondary events. The use of alternative antiplatelet therapies is also discussed (Smith et al. 2011).

Blood pressure control

The JNC-7 guidelines (Chobanian et al. 2003) have recommended the standard blood pressure goal of treatment of those with hypertension to be less than 140/90 mmHg, usually starting with a diuretic or beta blocker and considering additional therapy as needed to reach the goal, in most uncomplicated subjects. Recently, however, the American Diabetes Association modified the target blood pressure to less than 140/80 mmHg for most patients with diabetes (given the results of recent clinical trials such as the blood pressure substudy in ACCORD that did not demonstrate benefits from lower blood pressure goals in such patients) and continued the recommendation for using an ACE inhibitor or angiotensin receptor blocker as the preferred therapy due to their renal protective effects (Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults 2001). The JNC-7 guidelines additionally recommend beginning with combination therapy (including fixed dosage combinations) for people who are 20 mmHg or more systolic or 10 mmHg or more diastolic blood pressure away from the treatment goal. This takes into account the fact that, based on prior trials, for most patients, two or three medications will be needed to achieve adequate blood pressure control. Additionally, both the JNC-7 and AHA note a normal blood pressure optimal for the population to be less than 120/80 mmHg. A more recent report from members appointed to the JNC-8, however, has raised the threshold for treatment and goal to below 150/90 mmHg in adults aged 60 years and over (James et al. 2013), although this has not been endorsed by other recent guidelines.

Cholesterol and lipid control

Previous National Cholesterol Education Program (NCEP) goals for treatment of elevated LDL-cholesterol include achieving levels of < 100 mg/dL in those with the highest risk (pre-existing CHD or other CHD risk equivalents such as those with diabetes or other atherosclerotic disease or a calculated global risk of greater than 20 per cent for CHD in 10 years); less than 130 mg/dL in those with two or more risk factors; and <160 mg/dL in those with less than two risk factors (see section on risk assessment) (Expert Panel for Detection, Evaluation and Treatment of Blood Cholesterol 2001). Optional goals for lowering LDL-C to less than 70 mg/dL have been recommended for those at the very highest risk (e.g. pre-existing CVD plus diabetes or other uncontrolled risk factors, or with acute coronary syndromes) (Smith et al. 2011). The NCEP has also recommended non-HDL-C targets that are 30 mg/dL higher than the respective LDL-C targets for those with triglyceride levels of 200 mg/dL or greater as such people may have other atherogenic lipoproteins present and/or where the calculation of LDL-C is less accurate. While triglycerides less than 150 mg/dL and HDL-C levels of 40 mg/dL or greater in men and 50 mg/dL or greater in women are considered to be desirable, these are not specific therapeutic targets due to the lack of demonstrated benefit from clinical trials on CVD end points. Statins (HMG-CoA reductase inhibitors) are the preferred first-line therapeutic approach after lifestyle modification (see 'Exercise and physical activity' and 'Food and nutrition'), given the strength of the evidence from numerous clinical trials. There are currently no recommendations for the addition of fibrate therapy or niacin given the lack of incremental benefit over statins as shown by recent clinical trials. Most recent American College of Cardiology/American Heart Association Guidelines for the Management of Blood Cholesterol (Stone et al. 2013) have revised the approach for management of dyslipidaemia to include four statin eligible groups: 1) those with known atherosclerotic cardiovascular disease, 2) those with LDL-cholesterol of 190 mg/dL or higher, 3) those with diabetes, and 4) those with a 10-year pooled cohort risk of atherosclerotic cardiovascular disease of 7.5 per cent or greater (Stone et al. 2013) with LDL-C monitoring recommended only for evaluation of therapeutic response and adherence to statin therapy.

Cigarette smoking prevention and intervention

Smoking cessation has long been documented to reduce the risk of CVD. The risk of CHD is reduced by 50 per cent within 1 year of smoking cessation and to that of a never-smoker within 15 years. It is recommended that at each consultation with a healthcare provider the visit should be used as an opportunity to address the 5As of smoking cessation counselling which include 'Ask' (assess tobacco use at every visit), 'Advise' (strongly urge quitting), 'Attempt' (try to identify smokers ready to quit), 'Assist' (aid the patient in quitting), and 'Arrange' (for follow-up contacts). Interventions for smoking are varied. For youth, school, and community-based prevention programmes, state and federal initiatives, as well as cessation assistance are available. For adults, behavioural treatment, self-help approaches, and pharmacological therapy are used, with varying levels of success. For example quit rates vary from 6 per cent with physician advice only to 40 per cent in those who participate in group programmes (Luepker and Lando 2005).

Diabetes control

Recommendations for the treatment of diabetes to optimize cardiovascular risk reduction are available from a variety of sources. For example, the latest recommendations from the American Diabetes Association (Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults 2001) address antiplatelet therapy, glycaemic control, blood pressure control, lipid control (discussed earlier), weight control, and lifestyle management. Moreover, similar guidelines have been published by the European Association for the Study of Diabetes. Multifactorial intervention focusing on lipid, blood pressure, and glycaemic control has been shown to decrease the risk of future CVD events by more than 50 per cent (Gaede et al. 2008). This is a very important message given that in recent reports, only one tenth of those with diabetes have achieved target treatment levels for HbA1c, blood pressure, and LDL-C (Wong et al. 2012). While the goal of glycaemic control is a HbA1c level of less than 7 per cent in most uncomplicated diabetics, and even 6–6.5 per cent if achievable without side effects, given the results of recent trials, HbA1c levels of less than 8 per cent are accepted as an appropriate goal for those with pre-existing micro or macro-vascular disease or difficult-to-control diabetes (American Diabetes Association 2013). For optimal control, the recommended lipid targets from the American Diabetes Association are for the LDL-C to be less than 100 mg/dL (< 70 mg/dL if known macrovascular disease is present) and blood pressure of less than 140/80 mmHg for most people. More recent recommendations from the ACC/AHA have called for statin use in those with diabetes whose LDL-C is at least 70 mg/dL and a high-intensity statin in those who additionally have a 10-year ASCVD risk of 7.5 per cent or greater (Stone et al. 2014). Moreover, members appointed to the JNC-8 have recommended a threshold for treatment and goal for blood pressure to be set at 140/90 mmHg (James et al. 2014).

Exercise and physical activity

The ACC/AHA currently recommends 3 to 4 sessions a week, lasting on average 40 minutes per session, and involving moderate- to vigorous-intensity physical activity (Eckel et al. 2014). Regular physical activity can help maintain healthy blood pressure, weight, lipid levels, low levels of inflammation (C-reactive protein) and insulin sensitivity. A pedometer can be an effective tool for intervention with one guideline, for example, recommending walking at least 10,000 steps a day. For secondary prevention, a prescribed exercise programme is recommended, and participation initially in a supervised cardiac rehabilitation programme is advised for those recovering from a recent CHD event.

Food and nutrition

The National Cholesterol Education Program recommended the Therapeutic Lifestyle Change (TLC) diet which focuses on fresh vegetables and fruits and wholegrain products and consumption of monounsaturated fatty acids. A goal is to keep total fat intake to 25–35 per cent of total calories, monounsaturated fat intake to up to 20 per cent of total calories, fibre intake at 20–30 g per day, and balancing energy intake and expenditure. Use of stanol ester margarine supplements and fish oil supplementation can provide additional benefits on lipid levels and other cardiovascular risk

factors. Most recent ACC/AHA guidelines focus on recommending a dietary pattern that emphasizes intake of vegetables, fruits, and wholegrains; includes low-fat dairy products, poultry, fish, legumes, nontropical vegetable oils and nuts; and limits intake of sweets, sugar-sweetened beverages, and red meats (Eckel et al. 2014). Additional recommendations include consumption of no more than 2400 mg of sodium per day, or at least a 1000 mg reduction in daily sodium intake.

Specific additional recommendations for secondary prevention of CVD

Besides lipid control, blood pressure, antiplatelet, diabetes control, and lifestyle recommendations discussed in previous subsections, guidelines for secondary prevention also include therapy with a beta blocker, renin angiotensin and aldosterone system blockers, as well as annual influenza vaccination (Smith et al. 2011). Specific systems implemented in the hospital setting, such as pre-printed discharge instructions, reminders on charts (which can be automated in the case of electronic medical records systems) are key to ensure maximal adherence to recommended therapies for secondary prevention of CHD.

Conclusions

CVD accounts for the greatest burden of morbidity and mortality worldwide, both in developed and in developing countries. Key cardiovascular risk factors, including hypertension, cigarette smoking, high blood glucose, physical inactivity, obesity, and elevated cholesterol are (in that order) the top leading causes of death worldwide. It has been estimated that elimination of obesity, unhealthy diets, and physical inactivity could reduce up to 80 per cent of heart disease, stroke, and diabetes (Mendis et al. 2011).

In a recent Presidential Advisory (Smith et al. 2012) issued by the presidents of the World Heart Federation, European Society of Cardiology, AHA, and other leading cardiac societies, the call to reduce NCD deaths by 25 per cent by the year 2025 was noted (of which nearly half are due to CVD) and key global targets recommended for adoption were: (1) a 10 per cent reduction in the prevalence of insufficient physical activity, (2) a 25 per cent reduction in the prevalence of raised blood pressure, (3) a 30 per cent reduction in salt/sodium intake with a recommended goal of achieving lower than 5 g salt intake (2000 mg sodium) per day, and (4) a 30 per cent relative reduction in the prevalence of current tobacco smoking. Also receiving support was a reduction of saturated fat intake by 15 per cent, halving the prevalence of obesity, reducing alcohol intake by 10 per cent, reducing elevated cholesterol by 20 per cent, increasing by 50 per cent the number of people eligible to receive drug therapy to prevent heart attacks and strokes, and increasing availability of basic technologies and generic essential medicines for prevention of CVD.

Concerted global efforts aimed at coordinating care for those with pre-existing CVD (secondary prevention), primary prevention, identifying people with cardiovascular risk factors and getting them the necessary treatments, as well as primordial prevention aimed at prevention of obesity and other major risk factors in the first place, are critical for reducing the morbidity and mortality associated with CVD.

Cancer epidemiology and public health

Zuo-Feng Zhang, Paolo Boffetta, Alfred I. Neugut, and Carlo La Vecchia

Introduction to cancer epidemiology and public health

Classification of neoplasms is based on the International Classification of Diseases—Oncology (World Health Organization (WHO) 1976; Fritz et al. 2000) into topographical categories (according to the organ where the neoplasm arises) and morphological categories (according to the characteristics of the cells).

Further, they can be characterized by abnormal growth that can be distinguished in humans by localization, morphology, molecular characteristics, clinical behaviour, and response to therapy.

Benign and malignant tumours

Benign neoplasms represent localized growths of tissue with predominantly normal characteristics: in many cases they cause minor symptoms and are amenable to surgical therapy. They can be fatal because of their clinical importance when they occur in organs in which compression is possible and surgery cannot be easily performed (e.g. benign brain tumour), and when they produce hormones or other substances with a worsening systemic effect (e.g. adrenaline (epinephrine) produced by benign pheochromocytoma). Because relatively little is known about the distributions and causes of most benign neoplasms, they will not be further discussed in this chapter.

Malignant neoplasms are characterized by progressive growth of abnormal cells with structural and functional alterations with respect to the normal tissue. In some cases, the alterations can be so serious that it becomes difficult to identify the tissue of origin. A peculiarity of most malignant tumours is the ability to invade the nearby tissue, and to migrate and colonize other organs via blood and lymph vessel penetration and transport. The presence, extension, and control of metastases are often the critical factors to determine the success of therapy and the survival of cancer patients.

Carcinogenesis

Increasingly, neoplasms are characterized at the molecular level according to phenotypic aspects (e.g. presence of receptors, expression of genes) and genetic alterations (e.g. mutation in a given gene).

The understanding of the molecular and cellular mechanisms of carcinogenesis has greatly advanced in recent years. According to a widely accepted model, cells have to acquire six characteristics to become fully malignant (Hanahan and Weinberg 2011). These include the ability to produce growth signals (several known oncogenes mimic growth signalling), the lack of sensitivity to antigrowth signals (the retinoblastoma (RB) protein and its homologues play a key role in the ability of the cell to decide whether to proliferate, to be quiescent, or to enter into a post-mitotic state, based on external signalling), resistance towards programmed cell death or apoptosis (in many cases via inactivation of the p53 protein), immortalization (normal cells have a limited replication potential that is related to the length of the telomeres: in malignant cells, overexpression of telomerase circumvents it), stimulation of blood vessel production (by changing the balance of angiogenesis inducers and countervailing inhibitors), and ability to invade and metastasize. The acquisition of these neoplastic characteristics typically occurs by alterations of relevant genes, but an inability to maintain genomic integrity (so-called genomic instability, which includes reduced ability to repair DNA damage) is an additional feature of malignant cells, as accumulation of random mutations in genes involved in all the functions just mentioned would be a too rare event for the development of cancer during the normal lifespan. Inflammation also fosters multiple hallmark functions, and consequently promotes carcinogenesis. A final point to consider is the heterogeneity of neoplastic genetic alterations: the acquisition of the different biological capabilities of the neoplastic cell can appear at different times, and the particular sequence in which capabilities are acquired can vary widely, even among the same type of tumours. In addition, tumours contain a repertoire of normal cells, which contribute to create the tumour microenvironment.

Several inherited conditions carry a very high risk of one or several cancers. High-penetrance genes (or high-risk genes) are identified through family-based and other linkage studies. These conditions, however, are rare and explain only a small proportion of human cancers. Genetic factors, however, are likely to play an important role in interacting with non-genetic factors to determine individual cancer risk.

The long process of carcinogenesis justifies the efforts to develop and apply screening approaches for early detection of selected subclinical neoplasms in healthy individuals.

Cancer epidemiology and distribution

The development of cancer epidemiology has formed the basis for knowledge about the causes and the possible preventive strategies which has greatly advanced during the last several decades. The identification of the determinants of cancer relies on two complementary approaches, the epidemiological and the experimental.

Table 8.2.1 reports the ratio of the 80th to the 20th percentile as well as the highest to the lowest of the ranking of country-specific incidence rates of selected cancers, as estimated in the Globocan

2012 project (Ferlay et al. 2013). For overall cancer (excluding skin), the ratios of 80 per cent versus 20 per cent are 3.16 for men and 1.97 for women. For men, the lowest ratio of 80 per cent versus 20 per cent is 2.68 for non-Hodgkin's lymphoma. For women, the lowest ratio is 2.21 for ovary cancer. For gall bladder, lung, kidney, and testis cancers in men, multiple myeloma in women, malignant melanoma and Kaposi sarcoma for both genders, the ratios are over 10. This comparison is based on stable figures, but masks larger variations among very-high-risk and very-low-risk areas. The highest to

Table 8.2.1 Ratio of the 20th/80th percentile and highest/lowest in the ranking of country-specific estimated age standardized incidence rates of selected cancers (Globocan 2012)

Cancer	Men		Women

the lowest ratios in Table 8.2.1 represent extreme geographic differences that deserve epidemiological investigation into environmental and genetic factors in the development of cancer.

Analytical studies (case-control and cohort) have shown the causal role of specific exposures in the aetiology of several malignant neoplasms. One limitation of the epidemiological approach, which may prove of critical importance in trying to detect comparatively small increases in risk, as in the case of environmental pollutants, is that even in the best conditions it is impossible to confidently identify by epidemiological means an increase in risk smaller than about 10 per cent to 20 per cent and serious problems arise in the interpretation of increases below 50 per cent, as the biases inherent in any observational study are of at least this order of magnitude (Lagiou et al. 2008).

The identification of carcinogens via the laboratory relies on three types of tests: (1) long-term (often lifetime) carcinogenicity tests in experimental animals, most commonly rodents (mice, rats, and hamsters); (2) short-term tests assessing the effects of chemical agents on a variety of end points belonging to three general classes: DNA damage, mutagenicity, and chromosome damage; and (3) mechanistic tests, aimed at identifying the intermediate steps in the compound-specific carcinogenic process.

These tests are valuable to the extent that such effects may reflect underlying events in the carcinogenic process. Indeed, consistent positivity in tests measuring DNA damage, mutagenicity and chromosomal damage is usually regarded as indicating potential carcinogenicity of the tested agent. In addition, a number of factors, including hormones and overweight/obesity, show carcinogenic effects through non-genotoxic pathways, for which mechanisms of carcinogenesis are less well defined and their biomarkers are sparse (Boffetta and Islami 2013).

Results of laboratory tests constitute useful supporting evidence when adequate epidemiological data for the carcinogenicity of an environmental agent exists, but they become all the more essential when the epidemiological evidence is non-existent or inadequate in quality or in quantity. In the latter case, although no universally accepted criteria exist to automatically translate data from long-term animal tests or short-term tests to cancer risk in humans, an evaluation of the risk can be made on a judgemental basis using all available scientific evidence. This policy has been applied by the International Agency for Research on Cancer (IARC) in a systematic programme of evaluation of the carcinogenic risk of chemicals to man. Agents are commonly classified in group 1 when the evidence of their carcinogenicity in humans, derived from epidemiological studies, is considered sufficient, and are classified in group 2A when the evidence in humans is limited and the agent is an experimental carcinogen. Agents in group 2B include mainly experimental carcinogens for which the human evidence is inadequate or non-existent (IARC 2006). Since 1972, IARC has published 100 volumes presenting evaluations and re-evaluations for 968 chemical, physical, and biological agents and groups of agents, as well as exposure circumstances, such as occupations. A total of 111 agents have been classified in group 1, 66 in group 2A, and 285 in group 2B, 505 in group 3 (not classifiable as to its carcinogenicity to humans), and one in group 4 (probably not carcinogenic to humans). The complete list of agents, with their evaluations can be found on the Monographs website (IARC 2014).

Temporal changes in incidence rates, particularly when they take place over a few decades, are incompatible with a genetic explanation.

However, the possibility of environmental exposure changes as well as their possible interaction with genetic factors might contribute partially to temporal changes in incidence rates. Recorded incidence rates are affected by diagnostic changes and mortality rates are, in addition, affected by changes in treatment effectiveness; however, marked trends like the one for lung cancer mortality (Malvezzi et al. 2013) are most likely to reflect real changes in cancer rates, pointing to the importance of environmental factors.

Aetiological risk factors of cancer

A number of factors are associated with an increased risk of malignant neoplasms, but their importance varies in different settings and for neoplasms at different sites.

Tobacco smoking

This is the single major cause of human cancer worldwide (IARC 2004a). Tobacco-related cancers include cancers of the lung, nasal cavity, larynx, oral cavity, pharynx, oesophagus, stomach, liver, pancreas, colorectum, ovary, uterine cervix, kidney, and bladder, as well as of myeloid leukaemia. In high-income countries, tobacco smoking has been estimated to cause approximately 30 per cent of all human cancers (Doll and Peto 2005). In many medium- and low-income countries, the burden of tobacco-related cancer is still lower, given the relatively later start of the tobacco epidemics, which will result in a greater number of cancers in the near future. The IARC has classified tobacco smoking as a group 1 carcinogen and determined that 81 carcinogens in mainstream cigarette smoke have sufficient evidence for carcinogenicity in humans or laboratory animals, including 11 carcinogens in group 1, 14 in group 2A, and 56 in group 2B (IARC 2004a; Smith et al. 2003).

Diet and obesity

Despite considerable research efforts in recent years, the exact role of dietary factors in causing or protecting against human cancer remains largely unquantified. There is sufficient evidence of an increased risk of liver cancer with exposure to aflatoxin, a carcinogen in diet produced by some fungi in certain tropical areas. According to a recent comprehensive review on nutrition and cancer, high intake of red meat as well as processed meat were considered to have convincing evidence for an increased risk of colorectal cancer. There is convincing evidence that weight gain is associated with increased risk of cancers of the oesophagus (adenocarcinoma), pancreas, colorectum, post-menopausal breast cancer, endometrium, and kidney (World Cancer Research Fund and American Institute for Cancer Research (WCRF and AICR) 2007).

Alcohol drinking

As a group 1 carcinogen by IARC, alcohol drinking was considered to have sufficient evidence of carcinogenesis. Alcohol drinking at high levels increases the risk of cancers of the oral cavity, pharynx, larynx, oesophagus, liver, pancreas, colorectum, and female breast (Baan et al. 2007).

Infectious agents

These are considered the second most important factors for cancer risk in the world. Nine infectious agents have been classified as group 1 carcinogens (8.1 per cent), including six viruses associated with the origin of certain types of human cancers (Table 8.2.2): Epstein-Barr virus (EBV) with an attributable fraction (AF) of 97.9 per cent for nasopharyngeal cancer, 45.9 per cent for

Hodgkin's lymphoma, and 2.2 per cent for non-Hodgkin's lymphoma (NHL); human papillomavirus (HPV) with AFs of 100 per cent for cervical cancer, 55.7 per cent for anogenital cancer, 4.4 per cent for mouth and oral-pharyngeal cancers; hepatitis B virus (HBV) and hepatitis C virus (HCV) with an AF of 83.9 per cent for liver cancer; human immunodeficiency virus type 1 (HIV-1) with an AF of 12 per cent for NHL, and human T-lymphotropic virus type 1 (HTLV-1) with an AF of 1.1 per cent for NHL; as well as the bacterium *Helicobacter pylori* (AF of 63.6 per cent for stomach cancer), and parasites *Schistosoma haematobium* (AF of 3 per cent for bladder cancer) and *Opisthorchis viverrini* (liver flukes, AF of 0.4 per cent for liver cancer) (Parkin, 2006).

Occupation and pollution

While some carcinogens (e.g. *bis*-chloro methylethers) represent today a historic curiosity, exposure is still widespread for carcinogens such as asbestos, arsenic, and silica. Estimates of the global burden of cancer attributable to occupation in high-income countries result in figures on the order of 2–3 per cent (Steenland et al. 2003; Doll and Peto 2005).

Ionizing and non-ionizing radiation

The estimates of the contribution of ionizing radiation to human cancer in high-income countries are on the order of 3–5 per cent (Colditz et al. 2000; Doll and Peto 2005). Several neoplasms, in particular acute lymphocytic leukaemia, acute and chronic myeloid leukaemia, and cancers of the breast, lung, bone, brain, and thyroid are produced as a result of this radiation (IARC 2000).

Genetic factors

A number of inherited mutations of a high-penetrance cancer gene increase dramatically the risk of some, yet, in some populations, the number of cases attributable to them is small.

The global burden of neoplasms

The number of new cases of cancer which occurred worldwide in 2012 has been estimated at about 14,090,000 of which it was projected that 4,653,000 deaths occurred in men and 3,547,000 in women in the same year. In more developed and less-developed regions of the world, approximately 2,878,000 and 5,323,000 cancer deaths have resulted, respectively. Among men, lung, liver, stomach, colorectal, and oesophageal cancers are the most common causes of cancer deaths, while breast, lung, colorectal, cervix uteri, and stomach cancers are the most common causes of cancer deaths among women (GLOBOCAN 2012; Ferlay et al. 2013).

One complementary approach in assessing the global burden of neoplasms is to weigh the years of life with disability and add them to the years lost because of premature death (disability-adjusted life-years (DALYs)). According to the Global Burden of Disease Study 2010, lung cancer was responsible for 32.4 million DALYs, liver cancer for 19.1 million, breast cancer for 12.0 million, stomach cancer for 16.4 million, and colorectal cancer for 14.4 million (Murray et al. 2012).

Distribution, aetiology, and prevention of selected cancers

We report estimates for 2012 since more recent data are available only for selected regions and countries. The cancer site is ordered

based on numbers of specific cancer deaths based on Globocan 2012 (Ferlay et al. 2013).

Lung cancer

In 2012 lung cancer was the most frequent cancer in the world as there were 1,824,701 new lung cancer cases, accounting for approximately 13.0 per cent of the global cancer burden (GLOBOCAN 2012; Ferlay et al. 2013). Lung cancer was also the most common cause of cancer death, causing 1,589,800 deaths in 2012.

Incidence and mortality rates for lung cancer are approximately twice as high among men as among women. Lung cancer is the most common cancer in men worldwide (1.2 million new cases, 16.7 per cent of the total), with the highest age-standardized incidence rates observed in Central and Eastern Europe (53.5 per 100,000) as well as Eastern Asia (50.4 per 100,000) (GLOBOCAN 2012). The geographic pattern of incidence rates among women is slightly different, and generally lower, reflecting historic tobacco consumption patterns. The highest age-standardized incidence rates for women are observed in North America (33.8 per 100,000) and Northern Europe (23.7 per 100,000) (GLOBOCAN 2012). The geographical patterns in mortality closely follow those in incidence due to the high fatality and relative lack of variability in survival in different regions of the world.

The geographical and temporal patterns of lung cancer incidence are to a large extent determined by consumption of tobacco.

Principal histological types of lung cancer include squamous cell carcinoma, small cell carcinoma, adenocarcinoma, and large cell carcinoma; the last decades have witnessed a decrease in the predominant squamous cell carcinoma type and an increase in adenocarcinomas.

A carcinogenic effect of tobacco smoke on the lung was demonstrated in the 1950s and has been recognized by public health and regulatory authorities since the mid 1960s (IARC 2004a). The risk of lung cancer among smokers relative to the risk among never-smokers is on the order of over 20- to 40-fold. As compared to continuous smokers, the excess risk levels off in ex-smokers after quitting, but a small excess risk is likely to persist in long-term quitters throughout life. An association has been shown in many studies between exposure to involuntary smoking and lung cancer risk in non-smokers. The magnitude of the excess risk among non-smokers exposed to involuntary smoking is on the order of 20 per cent (IARC 2004a).

The UK Million Women Study demonstrated that the relative risks (RRs) of lung cancer were 10.5 for current smokers of ten cigarettes per day, 22.0 for 15, and 36.0 for 20 or more cigarettes per day (Pirie et al. 2013). Thus, even moderate smokers have substantial excess lung cancer mortality. This overall risk reflects the contribution of the different aspects of tobacco smoking: average consumption, duration of smoking, time since quitting, age at start, type of tobacco product, and inhalation pattern, with duration being the dominant factor.

The cumulative risk of lung cancer of a continuous smoker is 16 per cent and it is reduced to 10 per cent, 6 per cent, 3 per cent, and 2 per cent among those who stopped at ages 60, 50, 40, and 30, respectively (Peto et al. 2000). Among women in the United Kingdom, quitting smoking before age 40 years could avoid more than 90 per cent of the excess mortality caused by continuing smoking (Pirie et al. 2013). In the United States, stopping smoking

before the age of 40 years would reduce the risk of death associated with continued smoking by about 90 per cent (Jha et al. 2013).

An increase in tobacco consumption is paralleled some decades later by an increase in the incidence of lung cancer; similarly, a decrease in consumption is followed by a decrease in incidence, as observed in the United States. The highest incidence rates in men (> 80/100,000) are recorded among black people from the United States (American Cancer Society (ACS) 2013). Incidence rates are also high (> 40/100,000) in the North American and European countries where a significant decline is shown among US white men and among men in the United Kingdom and Northern Europe with the lowest revealed in Africa. Comparably, rates in women are high in these regions (> 30/100,000) apart from Africa and Central Asia where the prevalence of smoking only increased recently. A notable exception is China, with high rates being recorded despite a low prevalence of smoking (20.4/100,000) (GLOBOCAN 2012; Ferlay et al. 2013).

The risk of lung cancer is increased among workers employed in several industries and occupations.

For several of these high-risk workplaces, the agent (or agents) responsible for the increased risk have been identified. Of these, asbestos and combustion fumes are the most important. Occupational agents were responsible in the past for an estimated 5–10 per cent of lung cancers in industrialized countries, though this proportion is likely to be smaller in recent years.

Pulmonary tuberculosis has demonstrated an increased risk to lung cancer, although it is not coherent whether it is due to the chronic inflammatory status of the lung parenchyma or the specific action of the *Mycobacterium*. High levels of fibres and dusts might result in lung fibrosis (e.g. silicosis and asbestosis), along with chronic bronchitis and emphysema, conditions that also entail an increase in the risk of lung cancer.

Other concerns relate to the presence of urban air posing as a susceptible risk factor; however, the excess is unlikely to be larger than 20 per cent in most urban areas (Speizer and Samet 1994).

A protective effect noted against lung cancer is the intake of cruciferous vegetables, possibly due to their high content of isothiocyanates (IARC 2004b). However, despite the many studies of intake of other foods, such as cereals, eggs, and dairy products, for example, it is inadequate to formulate a judgement pertaining to evidence describing a carcinogenic or protective effect.

Currently, genome-wide association studies (GWAS) with large sample size have identified polymorphisms of genes located within 15q25 (*CHRNA3* and *CHRNA5*), 5p15.33 (*TERT-CLPTMIL*), and 6p21.33 (*BAT3*) to be associated with the risk of lung cancer. However, significant future studies are still needed to identify heritable risk factors and molecular pathways and signature of lung carcinogenesis (Marshall and Christiani 2013).

There is conclusive evidence that exposure to ionizing radiation increases the risk of lung cancer (IARC 2000). Atomic bomb survivors and patients treated with radiotherapy for ankylosing spondylitis or breast cancer are at moderately increased risk of lung cancer, while studies of nuclear industry workers exposed to relatively low levels, however, provided no evidence of an increased risk of lung cancer. Underground miners exposed to radioactive radon and its decay products, which emit α -particles, have been consistently found to be at increased risk of lung cancer (IARC 2001). The risk increased with estimated cumulative exposure and decreased with attained age and time since cessation of exposure

(Lubin et al. 1994). It was estimated that annual low-dose computed tomography (CT) scan was associated with a 5.5 per cent increased risk of lung cancer among smokers (Brenner, 2004).

Prevention of lung cancer

Control of tobacco smoking (including involuntary smoking) remains the key strategy for the prevention of lung cancer. Reduction in exposure to occupational and environmental carcinogens (in particular indoor pollution and radon), as well as increase in consumption of fruits and vegetables are additional preventive opportunities. The recent US National Lung Cancer Screening Trial reported a 20 per cent reduction of lung cancer mortality using low-dose CT scan; however, longer follow-up of this and other cohorts is needed to evaluate other possible side effects of the low-dose CT scan (Sarma et al. 2012; Field et al. 2013).

Cancer of the liver

The estimated worldwide number of new cases of liver cancer in 2012 is 782,000, of which 83 per cent are from developing countries (50 per cent from China alone) (GLOBOCAN 2012; Ferlay et al. 2013). Most low-income regions of the world, with the exception of South-Central and Western Asia, reflect a high incidence of liver cancer. The highest rates (above 30/100,000 in men and above 10/100,000 in women) are recorded in Eastern and South-Eastern Asia, Northern and Western Africa, and Melanesia. The lowest rates are in Northern Europe and South-Central Asia, where age-standardized rates are below 5/100,000 in men and 2.5/100,000 in women. Intermediate rates (5–10/100,000 in men) are observed in areas of Southern Europe and North America. Rates are two- to threefold higher in men than women, and the difference is stronger in high-incidence than in low-incidence areas.

Chronic infections with hepatitis B virus (HBV) and hepatitis C virus (HCV) are the main causes of HCC. The risk increases with early age at infection (in high-risk countries, most HBV infections occur perinatally or in early childhood), and the presence of liver cirrhosis is a pathogenic step. The estimated relative risk of developing HCC among infected subjects, compared to uninfected, ranged between 10 and 50 in different studies. On a global scale, the fraction of liver cancer cases attributable to HBV is 54 per cent, the one attributable to HCV is 31 per cent (Parkin 2006). Overall, over 75 per cent of liver cancer cases are related to infection (de Martel et al. 2012).

Ecological studies have shown that the incidence of HCC correlates not only with HBV and HCV infection, but also with contamination of foodstuffs with aflatoxins, a group of mycotoxins produced by the fungi *Aspergillus flavus* and *Aspergillus parasiticus*, which cause liver cancer in many species of experimental animals (Turner et al. 2012). Contamination originates mainly from improper storage of cereals, peanuts, and other vegetables and is prevalent in particular in Africa, South-East Asia, and China. The investigation of the carcinogenic role of aflatoxins in humans has been complicated by the inadequacy of traditional methods of exposure assessment (e.g. questionnaires). During the last decades, however, prospective studies have shown a strong association between biological markers of aflatoxin exposure in serum or urine and risk of subsequent liver cancer. A carcinogenic role for aflatoxins, in particular of aflatoxin B₁, has therefore been confirmed and shown to be independent from—and to interact

with—that exerted by HBV infection (London and McGlynn 2006).

(Alcoholic) cirrhosis is probably the most important risk factor for HCC in populations with low prevalence of HBV and HCV infection and low exposure to aflatoxins, such as North America and Northern Europe (La Vecchia 2007). The association between tobacco smoking and HCC is now established, with a RR of the order of 1.5 to 2 for tobacco smoking on liver carcinogenesis (IARC 2004a).

Use of oral contraceptives (OC) increases the risk of liver adenomas, and is associated with the risk of HCC, although the absolute risk is likely to be small. Case reports have associated use of anabolic steroids with development of liver cancer, but the evidence is not conclusive (Cibula et al. 2010).

Diabetes is also related to an excess risk of HCC, and the increased prevalence of overweight and obesity, and consequently of diabetes, in several populations may have had some role in recent unfavourable trends of HCC in North America and other areas of the world. Combined exposure to overweight at diabetes led to a RR of HCC of 4.75, after allowance for hepatitis, alcohol, and other recognized possible confounding factors (Turati et al. 2013a).

The excess risk of liver cancer associated with overweight/obesity and diabetes has been related to the development of non-alcoholic fatty liver disease (NAFLD) (Sanyal et al. 2010). NAFLD is characterized by excess fat accumulation in the liver, and ranges from isolated hepatic steatosis to non-alcoholic steatohepatitis (NASH), the more aggressive form of fatty liver disease, which can progress to cirrhosis and HCC. However, NAFLD/NASH increases HCC risk even in the absence of cirrhosis (Turati et al. 2013a).

Prevention of liver cancer

In high-prevalence areas, HBV vaccination has to be introduced in the perinatal period. In the last few decades, many countries from Asia, Southern Europe, and, to a lesser extent, Africa have expanded their national childhood vaccination programme to include HBV. Reduction of the incidence of liver cancer in young adults was observed in Qidong, a high risk area of liver cancer in China, because of both HBV vaccination and aflatoxin B₁ reduction in foods (Sun et al. 2013). A similar primary preventive approach is not available for HCV. Control of transmission is, however, feasible and medical treatment of carriers with interferon or newer antiviral drugs might represent an alternative approach, which is also available for HBV carriers.

Control of aflatoxin contamination of foodstuffs represents another important preventive measure. While this is easily achieved in high-income countries, its implementation is limited by economic and logistic factors in many high-prevalence regions. Control of alcohol drinking and tobacco smoking represent additional primary preventive measures.

Since about half of HCC, but not normal adult liver, secrete the fetal antigen α -fetoprotein, the detection of this marker has been proposed as a screening method. However, no population-based studies are currently available showing a decreased mortality from liver cancer in screened populations.

Cancer of the stomach

Accounting for approximately 951,000 new cases or 6.8 per cent of the global cancer burden, stomach cancer is the fifth most

frequent cancer in the world (GLOBOCAN 2012: Ferlay et al. 2013) and the third most common cause of cancer death worldwide (723,000 deaths in 2012, 8.9 per cent) in 2012. This marks a substantive decrease in incidence since 1975 when stomach cancer was the most common neoplasm worldwide. Incidence rates are about twice as high in men as in women, with age-standardized rates highest (above 35/100,000 in men and 10/100,000 in women) in Eastern Asia, Eastern and Central Europe, and South America. Low-incidence areas include Africa, North America, and Northern Europe. The majority of cases occur in developing countries (677,000), with over 40 per cent of all new cases coming from China alone (404,996).

An increased risk of gastric cancer is associated with *Helicobacter pylori* infection. The biological plausibility of a causal association is also supported by a strong association between *H. pylori* and precancerous lesions, including chronic and atrophic gastritis and dysplasia. Given that the prevalence of infection is very high, especially in developing countries and among older cohorts, *H. pylori* can explain a large proportion of all new cases of gastric cancer that occur, or over 5 per cent of all cancer cases globally (Parkin 2006). However, only a small fraction of infected individuals were diagnosed as having stomach cancer. Persistent *H. pylori* infection due to a combination of virulence factors and immune subversion and manipulation mechanisms is associated with gastric carcinogenesis (Salama et al. 2013).

Another important cause of stomach cancer is tobacco smoking. Smokers have a 50–60 per cent increased risk of stomach cancer, as compared to non-smokers. This relationship would indicate that smoking is responsible for approximately 10 per cent of all cases (IARC 2004a).

Throughout the world there is a consistent correlation between consumption of salt and salted foods and stomach cancer incidence. A large number of studies that have examined this relationship have generally found an increased risk of approximately twofold for frequent consumption of salt and salted foods. The relationship is biologically plausible, given that salt may lead to damage to the protective mucosal layer of the stomach.

A notably striking feature of gastric cancer is the dramatic decline in its incidence and mortality which has been observed in most high-income countries over the past century. The decline is apparent for both sexes, and has occurred earlier in countries which currently have a low risk. This continuous dramatic decline, as well as the results from migrant studies, suggests a strong environmental influence on the disease.

Reasons for the generalized decline in gastric cancer rates are complex and not completely understood. Almost certainly, these include a more varied and affluent diet and better food conservation, including refrigeration, as well as the control of *H. pylori* infection. Whether improved diagnosis and treatment have also played some role on the favourable trends in gastric cancer, particularly over most recent calendar periods, however, remains open to question.

GWAS on stomach cancer was mainly conducted in Asian populations. In Japanese populations, polymorphisms in the *PSCA* gene, which may possibly be involved in regulating gastric epithelial cell proliferation, were found to be associated with diffuse-type gastric cancer (Sakamoto et al. 2008). In Chinese populations, multiple variants at the 10q23 region (*PLCE1*) have been identified to be associated with cardia gastric cancer (Abnet

et al. 2010), and two novel susceptibility loci at 5p13.1 (*PTGER4* and *PRKAA1*) and 3q13.31 (*ZBTB20*) were found to be associated with non-cardia gastric cancer (Shi et al. 2011). These genes might regulate cell growth, differentiation, apoptosis and angiogenesis and be associated with the development of stomach cancer.

Other intervention trials conducted in a Chinese population known to be micronutrient deficient observed that a combination supplement of beta-carotene, vitamin E and selenium did result in a small reduction in the risk of stomach cancer (Blot 1997), but recent findings on the issue on other, better nourished populations, are largely negative (Plummer et al. 2007). More chemoprevention trials are needed for stomach cancer (Ford 2011).

Primary prevention of stomach cancer by dietary means is feasible by encouraging high-risk populations to decrease consumption of cured meats and salt preserved foods. Prevention may also be feasible through eradication of *H. pylori* infection, particularly in childhood and adolescence, and by avoiding mother to child transmission. Screening and early detection of stomach cancer have been developed in Japan with the use of X-ray photofluorography to identify early lesions, followed by gastroscopy.

Colorectal cancers

Cancers of the colon and rectum accounted in 2012 for an estimated 1,361,000 new cases and 694,000 deaths worldwide (GLOBOCAN 2012: Ferlay et al. 2013). They represent the third most frequent malignant disease in terms of incidence and the fourth for mortality. Colorectal cancer is the third most common cancer in men (746,000 new cases, 10 per cent total) and the second most common cancer in women (614,000 new cases, 9.2 per cent of the total).

The majority (55 per cent) of cases of colorectal cancer occur in high-income regions of the world, and geographical patterns are very similar in men and women. Generally, rates are slightly higher among men than women. The highest age-standardized rates are observed in Australia and New Zealand (44.8/100,000 for men and 32.2/100,000 for women), followed by western, southern, and northern Europe. There is considerable geographical variation in incidence of colorectal cancer, and the lowest rates in the world are observed in western Africa (4.5/100,000 for men and 3.8/100,000 for women) (GLOBOCAN 2012: Ferlay et al. 2013). A small increase in the incidence of colon cancer has been observed during the last few decades in most populations, but Western Europe over the last two decades (Fernandez et al. 2005; Siegel et al. 2014). Studies of migrant populations have shown that the risk of colon cancer approaches that of the country of adoption within one generation; the incidence is higher in urban than in rural populations.

The predominant histological type of malignant neoplasms of the colon is adenocarcinoma. This neoplasm is usually preceded by an adenomatous polyp, or adenoma, less frequently by a small area of flat mucosa exhibiting various grades of dysplasia. The malignant potential of an adenoma is increased by a surface diameter greater than 1 cm, by villous (rather than tubular) organization and by severe cellular dysplasia. Carriers of one adenoma larger than 1 cm have a two to four times increased risk of developing colon cancer; this risk is further doubled in carriers of multiple adenomas. On a topographical basis, the prevalence of adenomas detected during colonoscopy closely parallels the incidence of colon cancer.

Several studies have associated tobacco smoking with an increased risk of colonic adenoma. For colon cancer, a modest increased risk following prolonged heavy smoking has been shown in some of the largest prospective studies (IARC 2004a). Excessive alcohol consumption (50 g alcohol/day) has been associated with moderately increased risk of colon cancer (Baan et al. 2007).

Patients with ulcerative colitis and Crohn's disease are at increased risk of colon cancer. The overall RR has been estimated in the range of 5–20, and it is higher for young age at diagnosis, severity of the disease, and presence of dysplasia. The contribution of shared genetic and environmental factors in the genesis of the two inflammatory conditions and of colon cancer is not known. Diabetes and cholecystectomy have been associated with a moderate (1.5–2-fold) increased risk of (right-sided) colon cancer, possibly due to continuous secretion of bile. Patients with one cancer of the colon have a twofold risk to develop a second primary tumour in the colon or rectum, and the relative (though not the absolute) risk is greater for early age at first diagnosis. In women, an association has been shown also with cancers of the endometrium, ovary, and breast, possibly due to shared hormonal or dietary factors.

Several pathways which incorporate genetic instability (chromosomal instability (CIN) and microsatellite instability (MSI)), and inherited mutations of the adenomatous polyposis coli (*APC*) gene and mismatch repair genes pose as risk factors for colon cancer (Arends, 2013). More than 20 variants have been identified from regions at the 8q24 locus and genes within the TGF- β and Wnt signalling pathways. *CRAC1* on 15q13 and *SMAD7* on 18q21.1 were highlighted in multiple GWAS (Fernandez-Rozadilla et al. 2013; Peters et al. 2013). The majority of colorectal cancer GWAS were conducted in European descendants, with only two studies focused on East Asian populations (Cui et al. 2011; Jia et al. 2013).

Several rare hereditary conditions are characterized by a very high incidence of colon cancer. Familial adenomatous polyposis, due to inherited or *de novo* mutation in the *APC* gene on chromosome 5, is characterized by a very high number of colonic adenomas and a cumulative incidence of colon or rectal cancer close to 100 per cent by age 55. Gardner's syndrome, Turcot syndrome, and juvenile polyposis feature among the rarer diseases having this association. All these hereditary conditions, although very serious for the affected patients, account for no more than 1 per cent of colon cancers in the general population.

Lynch syndrome I is characterized by an increased risk of cancer of the proximal (right) colon, and is due to inherited mutation in one of two genes involved in DNA repair. Contrastingly, Lynch syndrome II has also an increased risk of extra-colonic neoplasms, mainly of the endometrium and the ovary. Overall, hereditary non-polyposis colon cancer may account for a sizeable proportion of cases of colon cancer in Western populations. In addition to these hereditary conditions, first-degree relatives of colon cancer patients have a two- to threefold increased risk of developing a cancer of the colon or the rectum.

Recent evidence from prospective studies provides only limited evidence in favour of a role of specific foods and nutrients (Marques-Vidal et al. 2006). The strongest evidence concerning dietary factors responsible for a substantial proportion of

colorectal cancers demonstrate an increased risk for high intake of meat and of smoked, salted, or processed foods (Huxley et al. 2009).

Vitamin D, and in particular its most active form, 25(OH) D, has been inversely related to colorectal cancer risk (Giovannucci 2005). The preventive effect is only possible when the vitamin D receptor (VDR) is present so that the mechanisms to increase VDR expression would enhance the preventive ability of vitamin D (Stubbins et al. 2012). Reduction of the incidence of colorectal cancer is also associated with the increased use of aspirin and other nonsteroidal anti-inflammatory drugs (Bosetti et al. 2012; Ferrández, et al. 2012). Additionally, hormone therapy in menopause and other female hormones, including OC, have been inversely related to colon cancer risks, and hence may also play some protective role (ACS 2011a).

Prevention of colorectal cancer

Increased physical activity, avoidance of overweight and obesity, reduced alcohol drinking, and quitting smoking are the main tools for the primary prevention of colorectal cancer. While aspirin use could prevent colorectal cancer as well, its use is not routinely recommended because of its spectrum of side effects.

Surveillance via flexible colonoscopy, involving removal of adenomas, is a secondary preventive measure. An additional approach consists in the detection of faecal occult blood. The method suffers from low specificity and, to a lesser extent, low sensitivity, in particular in the ability to detect adenomas. However, randomized trials have shown a reduced mortality from colorectal cancer after an annual test, although this is achieved at a high cost due to an elevated number of false positive cases. Current recommendations for individuals aged 50 and over include either annual faecal occult blood testing or one colonoscopic examination which does not need to be repeated in 10 years if results are normal (Boyle et al. 2003; ACS 2011a). Randomized trials have also demonstrated

the efficacy of sigmoidoscopy in reducing colorectal cancer mortality, primarily for the distal colon.

Cancer of the breast

Breast cancer is the most important cause of cancer death among women, and accounted for an estimated 521,000 deaths worldwide in 2012 (GLOBOCAN 2012; Ferlay et al. 2013). The incidence of breast cancer is relatively low (less than 25/100,000) in most countries of Middle Africa, in China, and a few other countries of East and South-Central Asia. The highest rates (70–90/100,000) are recorded in North America, Australia and New Zealand, Northern and Western Europe, as well as in the Bahamas, Argentina, Uruguay, Lebanon, and Armenia. The incidence of breast cancer has grown rapidly during the last few decades in many low-resource countries and slowly in high-income countries. In high-income countries, age-specific incidence rates increase sharply after age 45 and the rate in women aged 65+ is over 250/100,000. However, incidence rates in medium- and low-income countries are between 50 to 100/100,000 after age 45 (Fig. 8.2.1). Mortality rates remained fairly stable between 1960 and 1990 in most of Europe and the Americas; appreciable declines have occurred since the early 1990s. Incidence appears to increase linearly with age up to menopause, after which a further increase is less distinct (in high-income countries) or almost absent (in low-income countries). Women from high social class have consistently higher rates (about 30–50 per cent) than women from low social class.

The combined evidence from reproductive factors points towards an important role for endogenous hormones in breast carcinogenesis. A direct assessment of the role of oestrogens and testosterone is also available from recent prospective studies collecting data from biological samples. Oestradiol concentrations in the blood have been directly associated with breast cancer risk in post-menopausal women, whereas data are fewer and results are less consistent in pre-menopausal women. The association might be stronger with oestrogen and progesterone receptor positive

Fig. 8.2.1 Age-specific incidence of breast cancer by region of the world, 2012.

Source: data from Ferlay, J., et al. GLOBOCAN 2012 v1.0, *Cancer Incidence and Mortality Worldwide: IARC CancerBase No. 11*, International Agency for Research on Cancer, Lyon, France, Copyright © IARC 2013, available from <http://globocan.iarc.fr>.

tumours. Comparable findings have been reported for measures of testosterone and other androgens, but the data are inconsistent for all endogenous hormones across major cohort studies.

Less than 1 per cent of all cases of breast cancer occur in men. The incidence provides limited evidence of geographical and interracial variations, with no clear correlation with incidence in women. Conditions involving high oestrogen levels, such as gonadal dysfunction, alcohol abuse, and obesity, are likely risk factors for breast cancer in men. *BRCA2* mutations are more frequent than *BRCA1* in male familial breast cancers.

Women suffering from the two most common benign breast diseases, fibrocystic disease and fibroadenoma, carry a two- to three-fold increased risk of breast cancer. While these lesions are not likely to represent pre-neoplastic conditions, they share with breast cancer epithelial proliferation, linked to hormonal alterations.

A history of breast cancer in first-degree relatives is associated with a two- to threefold increased risk of the disease. Most of the role of familial history is likely to result from low-penetrance genes associated with hormonal metabolism and regulation, and DNA damage and repair. In the family linkage studies, breast cancer risk is greatly increased in carriers of mutations of several high-penetrance and low-frequency genes, including *BRCA1*, *BRCA2*, *PTEN*, and *TP53*. The mutations of these genes are associated with high risk of breast cancer, defined as inherited breast cancer syndrome. Although the cumulative lifetime risk in carriers of these genes is over 50 per cent, they are rare in most populations and explain only a small fraction (2–5 per cent) of total cases. There are exceptions, however, such as Ashkenazi Jews, among whom high-risk *BRCA1* or *BRCA2* mutations are responsible for an estimated 12 per cent of breast cancers. In addition, a group of low penetrance and low frequency DNA repair genes are related to moderate risk of breast cancer, including *CHEK2*, *ATM*, *BRIP1*, and *PALB2*. Both high- and moderate-risk genes account for approximately 25 per cent of cases with family history of breast cancer. Recent GWAS of breast cancer identified single nucleotide polymorphisms (SNPs) in several novel genes, including *TNRC9*, *FGFR2*, *MAP3K1*, *H19*, and *LSP1*, and these genes are related to metabolism, apoptosis, cell cycle regulation, and mitochondrial functions (Fanale et al. 2012).

There are similarities and differences in risk profiles between triple negative (TNBC) and ER+ breast cancer based on results of the Women's Health Initiative study. Similar risk factors included BMI, lack of physical activity, and breast density (Phipps et al. 2011a, 2012). Nulliparity was associated with decreased risk of TNBC but increased risk of ER+ breast cancer. Among parous women, the number of births was positively associated with TNBC and inversely associated with ER+ disease. Ages at menarche and menopause were modestly associated with risk of ER+ but not TNBC (Phipps et al. 2011b). Tobacco smoking was not associated with TNBC, but a risk factor for ER+ disease. Alcohol drinking was protective for TNBC, but a risk factor for ER+ breast cancer (Kabat et al. 2011).

Many lifestyle factors have been investigated as possible causes of breast cancer. Alcohol drinking is an established aetiological factor for breast cancer by IARC (Baan et al. 2007). Consumption of three or more alcoholic drinks per day carries an increased risk on the order of 30–50 per cent, with each daily drink accounting for about a 10 per cent higher risk. It is likely that both overweight and heavy alcohol drinking act on breast cancer through

mechanisms involving hormonal level or metabolism. Tobacco smoking does not carry an increased risk of breast cancer. A high level of physical activity, on the other hand, is likely to moderately decrease the risk in post-menopausal women (Kruk and Czerniak 2013). Studies of occupational factors and of exposure to organochlorine pesticides have failed to provide evidence of an aetiological role (Salehi et al. 2008).

Survival from breast cancer has slowly increased in high-income countries, such as the United States, Canada, Sweden, Cuba, and Japan, where improvements in screening practices and treatments have achieved 5-year survival rates of 80 per cent. In contrast, 5-year survival rates are between 60 per cent and 79 per cent in middle-income countries and below 60 per cent in low-income countries (Coleman et al. 2008). In the United States, breast cancer survival in the black population is consistently poorer than the white population (Allemani et al. 2013).

Prevention of breast cancer

Primary prevention of breast cancer has been attempted via nutritional intervention, involving reduction of energy intake, reduction of the proportion of calories from fat, and increase in fruit and vegetable consumption. No evidence of efficacy has been produced so far. However, control of weight gain, particularly of post-menopausal women, would have favourable implications in breast cancer risk.

The most suitable approach for breast cancer control is secondary prevention through mammography. The effectiveness of screening by mammography in women older than 50 years has been demonstrated, and programmes have been established in various countries (Boyle et al. 2003). The effectiveness in women younger than 50 is not yet demonstrated. Other screening techniques, including breast self-examination, have not been proven to reduce breast cancer mortality (US Preventive Services Task Force 2009).

Cancer of the oesophagus

Approximately 456,000 new cases and 400,000 deaths of oesophageal cancer occurred worldwide in 2012 (GLOBOCAN 2012; Ferlay et al. 2013). The geographical distribution of oesophageal cancer is characterized by very wide variations within relatively small areas. Very high rates (over 50/100,000) are recorded for both men and women in northern Iran, various provinces of eastern China, and certain areas of Kazakhstan (Wei et al. 2011; Igissinov et al. 2012). Intermediate rates in men (10–50/100,000) occur in South Africa, Eastern Africa, Eastern Asia, some provinces in China, and regions of Central Asia.

In all these high-risk areas, squamous cell carcinoma (SqCC) is the predominant histological type. Ethnic factors are suggested by the fact that populations at higher risk in Central Asia are of Turkish or Mongolian origin. Generally, rates in men are two- to fourfold higher than in women, although men and women have comparable rates in the very high-risk populations. In many high-risk areas, a decrease in the incidence of SqCC of the oesophagus has occurred during recent decades. In northern Europeans and white people in the United States, an increase in incidence was largely observed for adenocarcinoma of the lower oesophagus.

Tobacco smoking and alcohol drinking account for 90 per cent or more of the cases of oesophageal SqCC in Western Europe and North America. However, this proportion is lower in developing

countries, particularly in selected high-risk areas of Asia and South America. In a large case-control study in China, both tobacco smoking and alcohol drinking accounted for only 40 per cent of SqCC cases (Wu et al. 2011a).

The risk in heavy smokers relative to non-smokers is on the order of 5–10 in the Western populations. However, the RR estimate is much lower in the Asian populations. A recent large case-control study in Jiangsu, China reported that for individuals smoking more than 30 pack-years, the adjusted OR was 1.85 (1.49–2.29) (Wu et al. 2011b). A strong relationship has been shown for the duration of smoking and average consumption. Quitting smoking substantially reduces the risk: the RR declines within 5 years after quitting, remains substantially elevated at least 10 years after cessation, and declines by 40 per cent thereafter (Bosetti et al. 2006; Wu et al. 2011b). Thus, cessation of smoking could have an appreciable impact in reducing SqCC oesophageal cancer, and represents an obvious priority for prevention and public health purposes. Smoking black tobacco, high-tar, and hand-rolled cigarettes, as well as pipes, might exert a stronger effect than smoking other products. Chewing tobacco represents an important risk factor in India and southern Africa, but its role has not been confirmed in central Asia. In the latter region, smoking and eating opium may be (or may have been in the past) a reason for the high incidence rates (Shakeri et al. 2012). Snuff use has also been related to an excess risk of oesophageal cancer, with RR of 3.5 for SqCC in a Swedish cohort study based on ten non-smoking cases (Zendehdel et al. 2008; Lee 2011).

Areca nut chewing has been reported as an independent risk factor for SqCC in Asia and it may have additive interactions with tobacco smoking on the risk of the disease. Carcinogenic nitrosamines derived from areca nut are formed in the saliva of chewers and have been suggested as a risk factor for oral cancer and oesophageal cancer (Akhtar 2013).

In a meta-analysis of 40 case-control and 13 cohort studies, the pooled RRs for oesophageal SqCC were 1.38 for light drinking (< 12.5 g/day), 2.62 for 12.5–50 g/day, and 5.54 for greater than 50 g/day. Among never smokers, there was no association for light drinkers, but the RR rose to 3.1 for heavy drinkers. The association with alcohol might be modified by genetic factors such as aldehyde dehydrogenase 2 (*ALDH2*) polymorphisms in Asian populations (Islami et al. 2011; Wu et al. 2013). It is unclear whether there are differences in the carcinogenic potency of different alcoholic beverages, but the most common beverage in each population is the most strongly related one. A reduction in the excess risk of oesophageal SqCC is suggested 15–20 years after quitting. Furthermore, the effect of alcohol is independent from the effect of tobacco, and the interaction between the two exposures fits a multiplicative or additive model (Wu et al. 2011b).

Familial aggregation of oesophageal cancer has been occasionally shown, with joint segregation of a gene responsible for keratosis palmaris et plantaris (tylosis). Studies of families without the tylosis gene have not provided evidence of an important role of other high-penetrance genetic susceptibility factors in oesophageal cancer. However, recent GWAS studies in Chinese and Japanese populations implicate certain low-penetrance genes in oesophageal cancer development. Reported genes encoded enzymes involved in the metabolism of alcohol or tobacco, DNA damage repair, and other carcinogenesis pathways (Cui et al. 2009; Wang et al. 2010; Wu et al. 2011).

Other active carcinogens might be mycotoxins or N-nitroso compounds. Mycotoxins, including fumonisin B1, have also been detected in mouldy corn from high-risk areas in China and southern Africa. In addition, in Japan, eating bracken fern has been associated with an elevated oesophageal cancer risk. The elucidation of dietary factors implicated in oesophageal carcinogenesis, in particular the possible role of mycotoxins and N-nitroso compounds (including endogenously formed nitrosamines), would represent an important step in the understanding and prevention of this disease. Oesophageal cancer is related to ionizing radiation, in particular in women irradiated for breast cancer.

Reduced intake of fresh fruits and vegetables also appears to represent a risk factor for oesophageal cancer. A similar effect has been suggested for low intake of fish, and high intake of red and processed meat. In general, a dietary pattern rich in foods from animal origin and poor in vitamins and fibre appears to increase oesophageal cancer risk (Bravi et al. 2012). The available data do not, however, allow us to establish the potentially preventive role of specific micronutrients from fruits and vegetables, and the results of most chemo-preventive trials with retinol, riboflavin, vitamin E, zinc and selenium have failed to show a benefit.

Patients suffering from Plummer-Vinson syndrome, a sideropenic dysphagia due to deficit of iron, riboflavin, and other vitamins, had an increased incidence of hypopharyngeal and oesophageal cancers. Oesophageal cancer risk is also increased among coeliac disease patients, possibly because of nutritional deficiencies. Subjects with a family history of oesophageal cancer have about threefold excess risk after adjustment for tobacco and alcohol, and the RR rose to over 100-fold in heavy drinkers and smokers with positive family history in first-degree relatives (Garavello et al. 2005).

Adenocarcinoma occurs in the lower third of the oesophagus. Its incidence has sharply increased in the last four decades in most Western countries and has largely affected white people and high social class individuals. Barrett's oesophagus, a columnar metaplasia of the epithelium, is strongly associated with the subsequent development of adenocarcinoma. The main risk factor for Barrett's oesophagus and oesophageal adenocarcinoma is persistent reflux oesophagitis. It is predominantly seen in countries such as the United States or Scotland.

Overweight, obesity, lack of physical activity, and gastro-oesophageal reflux are featured risk factors in adenocarcinoma. In a meta-analysis of 22 studies (Turati et al. 2013b) compared with normal weight individuals, the pooled RR was 1.7 for overweight (body mass index (BMI) 25–30) and 2.3 for obese ones (BMI > 30). The increased prevalence of overweight and inactivity in North America and northern Europe may partly or largely, explain the increased frequency of adenocarcinoma (La Vecchia et al. 2002; Buas and Vaughan 2013).

Tobacco smoking has also shown a consistent association with oesophageal adenocarcinoma. The pooled RR from a meta-analysis of 33 studies was 1.8 for ever smokers and 2.36 for current smokers (Tramacere et al. 2011; Buas and Vaughan 2013). In contrast, there is no material association between alcohol drinking and oesophageal adenocarcinoma (Tramacere et al. 2012). Epidemiological evidence suggests a protective role for high intake of fruits and vegetables and an unfavourable role for intake of salty food.

Prevention of oesophageal cancer

Avoidance of tobacco smoking and elevated alcohol drinking remains the main preventive approach in reducing the burden of oesophageal SqCC in Western populations. Improved diet, in particular increased consumption of fresh fruits and vegetables, might also contribute to prevention. Avoidance of tobacco, control of obesity, increased physical activity, and treatment of reflux are considered the main issues for the prevention of oesophageal adenocarcinoma. Incomplete understanding of the role of other factors complicates the elaboration of preventive strategies in many high-risk regions, although decreasing intake of extremely hot drinks and slowing down eating speed might be important (Wu et al. 2011a).

Cancer of the pancreas

The great majority of malignant neoplasms of the pancreas are adenocarcinomas which originate from the exocrine portion secreting digestive enzymes. Rare pancreatic neoplasms include tumours (of uncertain clinical behaviour) of the endocrine portion, which secrete insulin and glucagon, as well as lymphomas and sarcomas.

Geographical and temporal variations exist in the sensitivity and specificity of clinical diagnosis and in the proportion of histological verification of pancreatic cancer cases. Even when comparing populations living in the same place at the same time (e.g. different social classes or age groups), differential access to healthcare might affect incidence and mortality data.

The median of 5-year survival was 5.2 per cent with a range of 2.2–9.6 per cent in countries with different economic status (ACS 2011b). Given its very poor survival, mortality rates closely parallel incidence rates. Rates are about 50 per cent higher in men than in women. An increase in incidence and mortality has taken place since the 1970s, particularly in Europe, that can be attributed in part to diagnostic improvements. However, incidence and mortality have levelled off and declined over recent years in men in the United States, Canada and United Kingdom (Levi et al. 2003; Ferlay et al. 2010; Malvezzi et al. 2013).

The disease accounts for an estimated 337,000 new cases in 2012, 55 per cent of which (187,000) occurred in more developed regions (GLOBOCAN 2012; Ferlay et al. 2013) where the highest rates are recorded among black people in the United States (about 16.9/100,000 in men and 13.9/100,000 in women) and European countries. The lowest rates, which may suffer from under-diagnosis, are recorded in South-Central Asia and Middle and Eastern Africa (below 2/100,000 in men and 1/100,000 in women). In the United States, the ratios of incidence of black versus white people were 1.26 and 1.36 for men and women, respectively (ACS 2013).

Urban populations have higher rates than rural ones, but this may again reflect differences in quality of diagnosis. Migrant population studies suggest that first-generation migrants from low- to high-risk areas experience, after 15 or 20 years, rates that are even higher than those of the country of migration, suggesting an important role of environmental exposures occurring late in life (Anderson 2006).

The best known risk factor for pancreatic cancer is tobacco smoking. The risk in smokers is two- to threefold higher than that in non-smokers, and a dose–response relationship and a favourable effect of quitting smoking have been shown in many

populations. It has been estimated that 20–30 per cent and 10 per cent of cases relating to pancreatic cancer in men and women are attributable to tobacco smoking (IARC 2004a; Iodice et al. 2008).

Some of the features of the descriptive epidemiology of pancreatic cancer (that is, a high incidence among black people in the United States as compared to a low incidence in Africa, and a higher risk among men and urban residents) can be explained by differences in smoking habits.

Several medical conditions have been studied with respect to their associations with subsequent risk of pancreatic cancer. A history of pancreatitis increases the risk more than tenfold, with little difference between the alcoholic and non-alcoholic forms of the disease. An increased risk has also been shown in several studies of diabetic patients; the RR is likely to fall in the range of 1.5–2 and is higher in the short term after diagnosis of diabetes. Gastrectomy patients are at a two- to threefold increased risk of pancreatic cancer; the association does not appear to be confounded by tobacco smoking.

A familial history of cancer of the pancreas is present in 8–10 per cent of patients, suggesting a possible role for genetic factors. Specific hereditary conditions carrying an increased risk of pancreatic cancer include the Li–Fraumeni syndrome, hereditary non-polyposis colon cancer, and a group of rare hereditary pancreatitis that involve deficiency in enzyme metabolism: these conditions, however, explain only a small proportion of cases in the general population.

Although there were six GWAS conducted on pancreatic cancer (four on Caucasians, one on Japanese, and one on Chinese), results were rather inconsistent and may need further confirmation (Amundadottir et al. 2009; Diergaarde et al. 2010; Low et al. 2010; Petersen et al. 2010; Willis et al. 2012; Wu et al. 2012a). Interestingly, one recent GWAS has identified genetic variation at the 11p15.4 region (*SBF2*) to be associated with overall survival in patients with pancreatic adenocarcinoma in both European and Asian populations (Wu et al. 2012b).

Studies have reported on the significant association between alcohol and pancreatic cancer; however, not all have addressed it. The current evidence suggests a possible weak effect of heavy alcohol drinking, but the evidence is not sufficient (Lucenteforte et al. 2012).

Nutritional and dietary factors have been suggested to be related to pancreatic cancer, including obesity and low physical activity, low intake of foods containing folate, red meat and a low intake of vegetables and fruit (WCRF and AICR 2007). The issue of nutrition, diet, and pancreatic cancer remains, however, largely undefined. Early reports of an association between coffee consumption and pancreatic cancer risk have not been confirmed by larger, more recent investigations (WCRF and AICR 2007). There is no effective cure for pancreatic cancer, with the exception of surgery for a small number of patients. Screening methods are not available. Primary prevention is the only available tool for this disease: avoidance of smoking is the major practicable way for reducing the number of cases. Control of obesity may be another potential preventive measure.

Head and neck cancer (cancers of oral cavity, pharynx, and larynx)

Tumours of the oral cavity, pharynx, and larynx are defined as a group named head and neck cancer because of shared histology

(the majority are squamous cell carcinoma) and aetiological factors (tobacco smoking and alcohol drinking). However, tumours of the lip, naso-pharynx, and salivary glands have distinct aetiological factors. We will focus our discussion on head and neck cancer in this section.

There were an estimated 600,000 new cases of cancers of the head and neck worldwide in 2012. The estimated number of deaths was 325,000 (GLOBOCAN 2012; Ferlay et al. 2013).

Cancer of the oral cavity, oropharynx, and hypo-pharynx

The incidence of cancers of the oral cavity varies over 20-fold between high-risk areas (e.g. Papua New Guinea, Maldives, Sri Lanka, Pakistan, Bangladesh, and India) and low-risk areas (e.g. China, Vietnam, Korea, and Haiti) (GLOBOCAN 2012; Ferlay et al. 2013). In all populations, rates in the oral cavity and pharynx in men exceed those in women by a factor of 2–8. Incidence rates of both sites increased in Europe and the Americas until the late 1980s and have levelled off or declined in most countries over the last decade. When looking at subsites within the oral cavity and the pharynx, cancer of the oropharynx and hypo-pharynx account for as many or more cases than cancer of the oral cavity in high-risk European populations. Cancers of the tongue, floor of the mouth, and other parts of the oral cavity represent the majority of cases in India and the United States.

Tobacco and alcohol are the most important risk factors for cancer of the oral cavity and pharynx. In Western populations, smoking represents the main use of tobacco, and the RRs of oral cancer among smokers compared to non-smokers are on the order of 3–10. The risk is higher for heavy smokers, long-term smokers, and smokers of black tobacco or high-tar cigarettes. Cigar and pipe smoking also poses a risk, while stopping smoking is followed by a decrease in risk. In India, chewing tobacco is the main risk factor for oral cancer, although *bidi* and cigarette smoking also contribute to the risk. In the United States and Europe, use of smokeless tobacco has also been implicated in the development of oral cancer (Boffetta et al. 2008).

Consumption of alcoholic beverages increases the risk of oral and pharyngeal cancer (Baan et al. 2007; Goldstein et al. 2010). Relative to abstainers and light drinkers, the RR in heavy drinkers is on the order of 10. The effects of tobacco smoking and alcohol drinking are multiplicative or larger; that is, the effect of exposure to both is close to or greater than the product of their individual effects. The combined effect of tobacco smoking and alcohol drinking accounts for almost 80 per cent of cancers of the oral cavity and pharynx in the West. Similarly, tobacco chewing and smoking and their combination are responsible for a large proportion of these cancers in India.

With reference to alcohol drinking, additional issues are worth discussing. First, oral cancer risks show a clear decline after stopping smoking. The pattern of risk after stopping drinking remains unclear, though it appears that an appreciable excess risk persists for several years. Second, although ethanol is the main carcinogenic ingredient in alcoholic beverages, it remains unclear whether different types of alcohol beverages have different influences on oral carcinogenesis. For example, spirits may be associated with higher risks than beer or wine (Boffetta and Hashibe 2006; Baan et al. 2007). This could explain some of the exceedingly high rates in countries like Hungary or Slovakia, where fruit-derived hard spirits are commonly consumed.

Human papilloma virus (HPV) DNA, detected in pre-neoplastic and neoplastic lesions of the oropharynx, is associated with over a 100-fold excess risk of oropharyngeal cancer (IARC 2007). The association is less strong for cancer of the oral cavity and is suspected as an aetiological factor for cancer of the hypo-pharynx. The role of HPV in head and neck cancer has become increasingly important since the 1990s in Europe and North America, mainly because of changes in sexual practices, while it remains less important in other regions of the world. The role of other oral cancer risk factors, as well as diagnosis and disease management, is smaller than that of tobacco or alcohol, and remains largely undefined. For example, dietary and nutritional factors, such as fruit and vegetable consumption, have shown a protective effect on oral cancer risk. Moreover, earlier diagnosis and improved treatment on oral cancer survival may have favourably influenced oral cancer death rates over time.

Poor oral hygiene and ill-fitting dentures are likely additional risk factors for oral cancer. Several occupations have been sporadically reported to confer an increased risk of oral and pharyngeal cancer. The evidence is consistent only for employment as a waiter and/or bartender, probably reflecting an increased consumption of alcohol and exposure to environmental tobacco smoke (ETS).

The role of genetic susceptibility in oral carcinogenesis is probably modest. High-risk families have been reported only occasionally. However, a role is likely for low-penetrance factors, such as increased sensitivity to mutagens and genetic polymorphisms of enzymes implicated in the metabolism of alcohol (alcohol dehydrogenase and aldehyde dehydrogenase) (Lewis and Smith 2005). GWAS in Caucasian populations have identified five variants, including three variants located within the alcohol dehydrogenase genes (*ADH7*, *ADH1B*, and *ADH1C*), one 4q21 variant located near DNA repair genes *HEL308* and *FAM175A*, and one 12q24 variant located near the *ALDH2* gene to be associated with head and neck cancer (Mckay et al. 2011). One GWAS with limited sample size conducted in an Indian population on chewing tobacco-related oral cancers did not identify any variant which reached genome-wide significance level (Bhatnagar et al. 2012). GWAS on head and neck cancer are relatively limited and replication studies in populations other than Caucasians are needed.

Prevention of oral and pharyngeal cancers

Avoidance of tobacco (smoking, chewing and snuffing) and avoidance of excessive alcohol drinking represent the main preventive measures for cancers of the oral cavity and pharynx. Primary prevention through prophylactic HPV vaccination is promising and would involve both girls and boys (Kreimer 2014). It is unclear whether additional benefits might be obtained from an increase in fruit and vegetable intake and improvement of oral hygiene. Avoidance of excessive exposure to solar radiation would represent the main preventive approach for lip cancer. In populations at high risk of nasopharyngeal cancer from China and possibly other countries, avoidance of salted fish and other preserved food, in particular as weaning food, should be recommended.

Oral inspection aimed to identify pre-neoplastic lesions might be an effective approach for secondary prevention of oral cancer. The inspection can be performed by medically certified professionals, but also, in particular in high-risk areas from developing countries, such as India, by specifically trained health workers. A large-scale preventive trial demonstrated a reduction in

oral cancer mortality during its 15-year follow-up, with larger reductions in those adhering to repeated rounds of screening (Sankaranarayanan et al. 2013).

Cancer of the larynx

More than 90 per cent of cancers of the larynx are squamous cell carcinomas; the majority originate from the supraglottic and glottic regions of the organs. The incidence in men is high (10/100,000 or more) in Cuba, Armenia, Hungary, Kazakhstan, Romania, Bulgaria and Moldova, while the lowest rates ($< 1/100,000$) are recorded in Benin, Burkina Faso, Cote d'Ivoire, Ethiopia, Guinea-Bissau, and Haiti. The incidence in women is $\leq 1/100,000$ in most populations. In most high-income countries, rates have declined in men over the last two decades. An estimated 157,000 new cases occurred worldwide in 2012, of which 88 per cent occurred among men (GLOBOCAN 2012: Ferlay et al. 2013). In addition, laryngeal cancer accounted for about 83,000 deaths.

Up to 80 per cent of cases of laryngeal cancer in high-income countries are attributable to tobacco smoking, alcohol drinking, and the interaction between the two factors (Olshan, 2006). The effect of tobacco, with risks in smokers on the order of 10 relative to non-smokers, seems to be stronger for glottic than supraglottic neoplasms. Studies in several populations have shown a dose-response relationship and a beneficial effect of quitting smoking (Pelucchi et al. 2008). Smoking black-tobacco cigarettes confers a stronger risk than smoking blond-tobacco cigarettes. Studies from India have also reported an effect of chewing tobacco-containing products. The effect of alcohol is stronger for supraglottic tumours than for tumours at other sites. It is not clear, however, whether different alcoholic beverages exert a different carcinogenic effect.

There are suggestions of a protective effect exerted by a high intake of fruits and vegetables, although the evidence is not conclusive and the data regarding specific micronutrients, such as carotenoids and vitamin C, are inadequate. Data concerning a possible effect of other foods are not consistent.

Occupational exposure to mists of strong inorganic acids, in particular of sulphuric acid, is an established risk factor for laryngeal cancer. An increased risk following inhalation of asbestos fibres is plausible. A possible effect has been suggested for other occupational exposures, including nickel and ionizing radiation, but the evidence is not conclusive.

An aetiological role of HPV infection in laryngeal cancer has been suggested. First, laryngeal papillomatosis, a condition characterized by multiple benign papillomas caused by infection with HPV types 6 and 11, confers an increased risk of laryngeal cancer. Second, a meta-analysis of studies assessing the presence of HPV DNA reported strong associations between HPV infection and laryngeal squamous cell carcinoma, with a summary odds ratio (OR) of 5.39 (95 per cent confidence interval (CI) 3.25–8.94). A similar association was observed for HPV-16 (OR 6.07; 95 per cent CI 3.44–10.70) (Li et al. 2013).

There is no evidence of strong genetic factors in laryngeal carcinogenesis. However, polymorphisms for enzymes implicated in the metabolism of alcohol and tobacco and DNA repair might represent susceptibility factors (Lewis and Smith 2005; McKay et al. 2011).

Survival from laryngeal cancer is fair. Five-year survival rates are on the order of 65 per cent in high-income countries and 40 per cent in developing countries (Ellis et al. 2012). These

patients are at very high risk of developing a second primary tumour in the oral cavity, pharynx, and lung. While shared risk factors are likely to play an important role, it is plausible that host factors are also partially responsible. For example, an increased sensitivity to mutagens has been shown in lymphocytes of laryngeal cancer patients, in particular those with multiple tumours, as compared to controls. A report indicated that *p53*-related genes are related to susceptibility of second primary cancer in patients with primary head and neck cancer (Jin et al. 2013).

Control of tobacco smoking and excessive alcohol drinking, possibly together with an increased intake of fruits and vegetables, would prevent the majority of cases of laryngeal cancer in most populations. Control of exposure to known and suspected occupational carcinogens is an additional measure for exposed workers. Prophylactic HPV vaccination is promising (Kreimer 2014). No screening methods are currently available for laryngeal cancer.

Prostate cancer

Prostate cancer is the second most common cancer and the fifth leading cause of death from cancer in men worldwide with an estimated 1,111,000 newly diagnosed cases and 307,000 deaths in 2012 (GLOBOCAN 2012: Ferlay et al. 2013). Almost 70 per cent of the cases (759,000) occurred in more developed regions. It is the most common malignant neoplasm in men from Australia/New Zealand (111.6/100,000), North America (97.2/100,000), and Western Europe (94.9/100,000). The incidence is 69.5/100,000 in high-income regions and 14.5/100,000 in low- and middle-income regions. The rates remain the lowest in South-Central Asia (4.5) and Eastern Asia (10.5) (GLOBOCAN 2012: Ferlay et al. 2013). Mortality rates of prostate cancer show less variability among regions, suggesting that the number of non-fatal cases diagnosed in different countries varies depending on screening and other diagnostic procedures.

The incidence of prostate cancer is highly dependent on the adoption of prostate-specific antigen (PSA) testing. Prostate cancer incidence has shown substantial changes following the introduction of PSA testing, with major increases due to the detection of large number of prevalent cases, followed by substantial declines. The changes in trends have been much smaller for mortality, but both in the United States and in Western Europe, peak rates were observed in the early 1990s, with a levelling off and a decline thereafter, approaching 20 per cent in the EU (Bosetti et al. 2011).

The recent trends in prostate cancer mortality in Europe are consistent with a favourable impact of improved diagnosis, as well as of advances in therapy, on prostate cancer mortality in Western Europe and North America (Bosetti et al. 2011).

Prospective studies failed to provide convincing evidence of an increased risk linked to increased level of testosterone or other sexual hormones. Similarly, an increased risk of prostate cancer was reported in retrospective studies following a history of benign prostatic hypertrophy, but no excess risk was found in prospective studies. If an association exists between prostatic hypertrophy and cancer, it can be due to shared aetiological factors or to a common pathological process.

Carriers of *BRCA1* and *BRCA2* mutations have a four- to fivefold increased risk of prostate cancer with especially a two- to threefold increased risk of developing the same neoplasm in first-degree relatives. It is also similarly identified in small magnitudes in breast

and colon cancers. Genetic variants entailing an increased risk of prostate cancer have been identified within the 8q24 and possibly the 17q12 region (Amundadottir et al. 2006; Gudmundsson et al. 2007; Haiman et al. 2007; Yeager et al. 2007). This was also confirmed recently, in over 20 GWAS studies, including chromosome 3, 7, 17, 22, and X, and explains 13 per cent of the total genetic variance of prostate cancer risk (Kim et al. 2010; Chen et al. 2013). Although the majority of the studies were conducted in European descendants, the 8q24 region continues to be the most implicated region in prostate cancer risk in other race/ethnic groups, including Japanese, Latinos, Chinese, and African American (Takata et al. 2010; Ishak and Giri 2011; Cheng et al. 2012; Xu et al. 2012).

It has been suggested that the risk of the disease increases with number of sexual partners and number of encounters with prostitutes, and with a previous history of syphilis and gonorrhoea. Serological studies of HPV 16 and HPV 18 have shown an increased risk among positive subjects, but the findings are inconsistent. It is not clear at present, however, whether syphilis and HPV are causal factors or markers of infection with sexually transmitted agents, and hence general markers of inflammation.

A possible protective role of high intake of vegetables has been suggested in a few studies; high intake of meat, dairy products, total fat, and saturated fat might represent a risk factor. The evidence concerning other dietary factors, including fruit intake and intake of specific micronutrients, is, however, largely inconclusive at present. These include lycopene, a retinoid present in particular in tomatoes which has been found to be associated with a reduced risk in a few (but not other) studies, and calcium which has been associated with an elevated risk, possibly on account of its influence on vitamin D balance. There is, in fact, biological evidence that the most active form of vitamin D, 25(OH) D, has a favourable role on prostate cancer, but epidemiological data are inconsistent (Giovannucci 2005; Gilbert et al. 2011). Vitamin D may prevent prostate cancer progression, and hence the most aggressive forms of the disease (Li et al. 2007), and there is also an observation by a meta-analysis that an increased risk exists among individuals with elevated serum level of insulin-like growth factor 1 (Chen et al. 2009). An increased risk of the advanced prostate cancer has been reported among subjects with a high BMI (Platz and Giovannucci 2006; Discacciati et al. 2012). Data on nutrition, diet, and prostate cancer are, however, largely inconsistent.

The wide geographical variability of prostate cancer suggests that environmental factors likely related to diet and other lifestyle factors, such as physical activity, are important determinants of the disease. Primary prevention, however, is hampered by the fragmentary knowledge of its precise causes. Secondary prevention has been proposed, based on measurement of PSA and digital rectal examination. There is little evidence from controlled trials that either procedure decreases the mortality from prostate cancer (Boyle and Brawley 2009; Welch and Albertsen 2009). Despite this lack of evidence, these procedures, in particular the PSA testing, have gained popularity in many countries, and are the cause of the steep increase in number of diagnosed cases since the mid 1980s in North America and other high-income countries. It is unclear how much of the decrease in mortality reported since the mid 1990s in the United States and in Western Europe can be attributed to a beneficial effect of (unplanned) use of PSA testing, but it is likely due mainly to improved management and treatment of the disease, including better surgery, radiotherapy

and medical therapy. The United States Preventative Services Task Force (USPSTF) made a final recommendation against PSA based screening for healthy men because there is 'moderate or high certainty that the service has no benefit or that the harms outweigh the benefits'. The USPSTF issued a Grade D to discourage the use of the test by men of all ages for screening purpose.

Cancer of the uterine cervix

The estimated worldwide burden of cervical cancer in 2012 was approximately 528,000 new cases and 266,000 deaths (GLOBOCAN 2012; Ferlay et al. 2013). Cervical cancer is a major public health problem in less developed regions, where about 84 per cent of cases (445,000) and 86 per cent of deaths (230,000) occurred in 2012. The number of estimated cervical cancer deaths in these regions is third to breast cancer (324,000) and lung cancer (281,000) among women (Ferlay et al. 2013). Incidence rates are high (over 30/100,000) in Eastern, Southern, and Middle Africa and Melanesia. Rates are lowest in Australia/New Zealand (5.5), Western Asia (4.4), Middle-East (6.4), Northern American (6.6), and Northern Africa (6.6). Incidence and mortality rates have decreased steadily in high-income countries, but an upturn in incidence had been observed among young women in a few of these. Few data on temporal trends are available from middle- and low-income countries, but incidence has likely decreased during recent decades in those areas of the world, too. In high-income countries, rates increase up to age 60, while in middle and low-income countries there is little increase above age 50. Cervical cancer hits preferentially women of lower education and social class.

Most cervical cancers originate from the area of squamous metaplasia called the transformation zone, which is adjacent to the junction between the columnar epithelium of endometrial origin and the characterizing epithelium of vaginal origin. Most invasive cancers are SqCC or mixed adeno-squamous tumours. Invasive carcinoma is preceded by inflammatory and condylomatous atypia, mild dysplasia (also called cervical intraepithelial neoplasia of grade 1, or CIN 1), moderate dysplasia (CIN 2), severe dysplasia and carcinoma *in situ* (CIN 3) (Schiffman and Hildesheim 2006).

Chronic infection with HPV is a necessary cause of cervical cancer. Using sensitive molecular techniques, virtually all tumours are positive for the HPV (Clifford et al. 2005). Different types of HPV exist, and those associated with cervical cancer are mainly types 16, 18, 31, 45, and 58 where HPV 16 is the main cervical carcinogen in most populations, while the distribution of other types varies by geographical region (Fig. 8.2.2). The host response to HPV infection is important in determining its carcinogenic effect; immunosuppression, as present in transplanted patients and HIV infected women, increases the risk of dysplasia, carcinoma *in situ*, and invasive neoplasms.

Sexual histories of women (early age at first intercourse and increased number of sexual partners) and of their male partners (high number of sexual partners, presence of genital diseases, and contact with prostitutes) are risk factors for cervical cancer in many populations. They reflect an increased likelihood of HPV infection, as well as the duration of HPV infection. As for most carcinogens, in fact, duration of exposure is the major determinant of subsequent cancer risk (Plummer et al. 2012).

Tobacco smoking has also an independent effect on cervical carcinogenesis with a RR of 1.5–1.6 for current smokers, also

Fig. 8.2.2 Most common HPV types in 14,097 cases of invasive cervical cancer by region.

Reprinted from *The Lancet*, Volume 366, Issue 9490, Clifford, G.M. et al. Worldwide distribution of human papillomavirus types in cytologically normal women in the International Agency for Research on Cancer HPV prevalence surveys: a pooled analysis, pp. 991–998, Copyright © 2005, with permission from Elsevier, <http://www.sciencedirect.com/science/journal/01406736>.

once HPV infection is taken into account (IARC 2004a; Moralejo 2009). A possible protective effect of a diet rich in fruits and vegetables has been suggested in a few studies, but the role of diet on cervical cancer risk is probably modest and largely undefined.

Cytological examination of exfoliated cervical cells (the Papanicolaou smear, Pap test) is effective in identifying precursor lesions, resulting in a substantial decrease in incidence of and mortality from invasive cancer. Cytological smears are not largely applicable, however, in countries with limited availability of cytologists and pathologists, including many countries with a high prevalence of HPV infection and high incidence of invasive cancer. Alternative approaches for secondary prevention have therefore been proposed, including visual inspection of the cervix with possible enhancement of precursor lesions by acetic acid (VIA). VIA performs as well as the Pap test in terms of sensitivity and specificity and can be used in low-income areas (Bradford and

Goodman 2013). Use of HPV-DNA testing appears now, however, to be more specific and sensitive than the Pap test, and is, therefore, likely to replace the Pap smear as the first screening method in the near future. The primary method for prevention of cervical cancer for future generations, however, is likely to become HPV vaccination. One vaccine against HPV 16, 18 (as well as 6 and 11, linked to genital warts) is now available, and another against HPV 16 and 18 only (FUTURE II Study Group 2007). Vaccines including larger numbers of HPV strains (i.e. eight strains) are in the late stage of testing. The final impact of the effect of such vaccination is complicated by the geographical variations in the distribution of HPV types. In addition, smoking cessation may play a role since tobacco smoking is an independent aetiological factor of cervical cancer.

Studies of infection with other agents, in particular *Chlamydia* and herpes simplex 2, have failed to provide consistent evidence of

an effect independent from HPV. An increased risk, on the order of twofold, has been detected among long-term current or recent users of OC, which is not completely explained by sexual behaviour or HPV infection. However, there is no residual association 5–10 years after stopping OC use. Consequently, the public health implications of OC use on cervical cancer risk are limited in time (La Vecchia and Bosetti 2003; Cibula et al. 2010). Condom and (perhaps) diaphragm use, on the other hand, exert a protective effect, possibly via prevention of HPV infection.

GWAS identified multiple loci within the MHC region at 6p21.3 to be associated with cervical cancer, indicating the importance of impaired immune response in cervical cancer development (Chen et al. 2013; Shi et al. 2013).

Principles of primary and secondary cancer prevention

Primary prevention

Many determinants of malignant neoplasms, including UV radiation, ionizing radiation, tobacco smoking, alcohol drinking, overweight, a number of viruses and parasites, and a number of chemicals, industrial processes and occupational exposures, are sufficiently well established to constitute logical priorities for preventive action. Two more reasons add weight to this priority: some of the agents are responsible for sizeable proportions of the cancers occurring today, and for many agents it is, in principle, feasible to reduce or even to completely eliminate exposure. If this is taken as the objective of preventive action, some practical points are helpful in guiding such action.

First, although epidemiological data in most cases do not allow a direct estimate of the risk of cancer at low doses, it is reasonable (at least from a preventive point of view) to assume that the dose (exposure)–risk relationships for agents acting through damage to DNA are linear with no threshold (Peto et al. 1991). Second, the carcinogenic effect is not equally dependent on the dose rate (dose per unit of time) and on duration of exposure. For example, in regular smokers, the incidence rate of lung cancer depends more strongly on duration of exposure, increasing with the fourth power of it, than on dose rate, increasing only with the first or second power of it.

Furthermore, as illustrated earlier, the carcinogenic process may be represented as a succession of stages, taking place in the time span from first exposure to a carcinogenic agent to the appearance of clinical cancer. In its simplest form, as first brought out in mouse skin carcinogenesis experiments, the multistage process reduces to two stages: an irreversible ‘initiation’ stage inducing malignant cells, and a ‘promotion’ stage which propagates these cells into a malignant growth. A third stage of ‘progression’, characterized by an increased rate of growth and metastases, as well as an increase in chromosomal changes in the cell, has also been observed. Formal statistical multistage models of carcinogenesis have provided a useful framework to interpret on a common basis of (postulated) mechanisms both experimental and epidemiological observations. As the stages are assumed to occur in a specific sequence, some may be described as ‘early’ and some as ‘late’. Epidemiological observations indicate that, for example, smoking has both an early stage effect, as indicated by the existence of a minimum interval of several years before an increase in risk of

lung cancer becomes manifest, and a late stage effect, as indicated by the decrease in risk (with respect to continuous smokers) soon after stopping smoking.

Cancer prevention strategies have evolved from a predominant environmental and lifestyle approach to a model that matches individual-oriented actions with public health interventions. Advances in identifying, developing, and testing agents with the potential either to prevent cancer initiation, or to inhibit or reverse the progression of initiated lesions support this approach. Encouraging laboratory and epidemiological studies, along with studies of secondary end points in prevention trials, have provided a scientific rationale for the hypothesis. Promising results have been reported for various types of cancer, in particular among high-risk individuals (Greenwald 2005; Dunn and Greenwald 2010).

Secondary and chemoprevention

Given the limitations still constraining the primary prevention of many cancers, early detection needs to be considered as a secondary and alternative option, based on the reasonable expectation that the earlier the diagnosis and the stage at which a malignancy is discovered, the better the prognosis. This implies that an effective treatment for the disease exists and that the less advanced the cancer at the pre-clinical stage, the better the scope for treatment, and the better the prognosis. This latter aspect cannot be taken for granted.

Before a screening programme can be adopted on a large scale, a number of other requirements need to be fulfilled. First of all, a screening test (that is, a relatively simple and rapid test aimed at the presumptive identification of pre-clinical disease) must be available that is capable of correctly identifying cases and non-cases. In other words, both sensitivity and specificity should be high, approaching 100 per cent. While high sensitivity is obviously important, given that the very purpose of screening is to pick up, if possible, all cases of a cancer in its detectable pre-clinical phase, it is specificity that plays a dominant role in the practical utilization of the test within a defined population. As the prevalence of a pre-clinical cancer to be screened in well-defined populations is often in the range of 1 to 10 per 1000, if a test is used with a specificity of 95 per cent, then 5 per cent of results will be false positives. In other words, for every case which will turn out at the diagnostic work-up to be a true cancer (assuming 100 per cent sensitivity), there will be 5–50 cases falsely identified as such and ultimately found not to be cancers. This situation is likely to prove unacceptable due to too high psychological and economic costs. One solution is an increase in specificity, for example, by developing better tests or combinations of tests, or by changing the criterion of positivity of a given test to make it more stringent (this necessarily decreases sensitivity). In addition, one might select populations with relatively high prevalence of the cancer (‘high-risk’ groups), so as to increase the number of the true positives. Whatever the group on which the programme operates, additional requirements are that the test is safe, easily and rapidly applicable, and acceptable in a broad sense to the population to be examined. It has also to be cheap, but what is or is not cheap is better evaluated within a cost-effectiveness analysis of different ways of preventing a cancer case or death, an issue not further discussed here.

If these requirements are met, still nothing is known about the possible net benefit in outcome deriving from the screening

programme (in fact, screening test plus diagnostic work-up plus treatment, as applied in a given population). To evaluate benefit, several measures of outcome can be assessed. An early one, useful but not sufficient, is the distribution by stage of the detected cancer cases which, if the programme is ultimately to be beneficial, should be shifted to earlier, less invasive stages of the disease in comparison with the distribution of the cases discovered through ordinary medical care. A second measure of outcome is the survival of cases detected at screening compared with the survival of cases detected through ordinary medical care. This is a superficially attractive but usually equivocal criterion, to the extent that screening may only advance the time of diagnosis (and therefore the apparent survival time), without postponing the time of death ('lead time bias'). A final outcome (and the main test of the programme) is the site-specific cancer mortality in the screened population compared with the mortality in the unscreened population.

Correct, unbiased comparison of this outcome, and thus unbiased measure of the effect of the screening programme, should in principle be made within the framework of a randomized controlled trial, in which two groups of subjects are randomly allocated to the screening programme and to no screening (that is, receiving only the existing medical care system) or to two alternative screening programmes, for instance, entailing different tests or different intervals between periodical examinations. Unfortunately, largely due to pressures to adopt on a large scale screening programmes hoped to be effective, a situation has often arisen where withholding screening to a group has been regarded as unethical or socially unacceptable, thus preventing the conduct of a proper experiment. Very few randomized trials evaluating the

effectiveness of screening programmes are available. Comparisons are made through non-randomized experiments or through observational studies.

In addition to lead-time bias, three types of bias are peculiar to the assessment of screening programmes. Because of self-selection, persons who elect to receive early detection may be different from those who do not: for instance, they may belong to better educated classes, be generally healthier and health conscious, and this could produce a longer survival independent of any effect of early detection. In addition, cancers with longer pre-clinical phases, which may mean less biological aggressiveness and better prognosis, are, in any case, more likely to be intercepted by a programme of periodic screening than cancers with a short pre-clinical phase, and a rapid, aggressive clinical course (length bias). Finally, because of criteria of positivity adopted to maximize yield of early cases, a number of lesions which in fact would never become malignant growths are included as 'cases', thus falsely improving the survival statistics (over-diagnosis bias) (Croswell et al. 2010).

Chemoprevention can also be considered for primary and secondary prevention of cancer, but data are negative or inconsistent for most micronutrients or other substances considered.

Conclusions

Neoplasms are a group of diverse diseases with complex distributions in human populations and with different aetiological factors. Current knowledge of the causes of human neoplasms and the development of control strategies have led to the elaboration of lists of recommendations for their prevention (Box 8.2.1).

Box 8.2.1 European Code Against Cancer (Boyle et al. 2003)

Many aspects of general health can be improved, and many cancer deaths prevented, if we adopt healthier lifestyles:

1. Do not smoke; if you smoke, stop doing so. If you fail to stop, do not smoke in the presence of non-smokers.
2. Avoid obesity.
3. Undertake some brisk, physical activity every day.
4. Increase your daily intake and variety of vegetables and fruits: eat at least five servings daily. Limit your intake of foods containing fats from animal sources.
5. If you drink alcohol, whether beer, wine, or spirits, moderate your consumption to two drinks per day if you are a man or one drink per day if you are a woman.
6. Care must be taken to avoid excessive sun exposure. It is specifically important to protect children and adolescents. For individuals who have a tendency to burn in the sun, active protective measures must be taken throughout life.
7. Apply strictly regulations aimed at preventing any exposure to known cancer-causing substances. Follow all health and safety instructions on substances which may cause cancer. Follow advice of National Radiation Protection Offices.
8. There are public health programmes that could prevent cancers developing or increase the probability that a cancer may be cured. Women from 25 years of age should participate in cervical screening. This should be within programmes with quality control procedures in compliance with *European Guidelines for Quality Assurance in Cervical Screening*.
9. Women from 50 years of age should participate in breast screening. This should be within programmes with quality control procedures in compliance with *European Guidelines for Quality Assurance in Mammography Screening*.
10. Men and women from 50 years of age should participate in colorectal screening. This should be within programmes with built-in quality assurance procedures.
11. Participate in vaccination programmes against hepatitis B virus infection.

Reproduced from Boyle P., et al. European Code Against Cancer and scientific justification: third version, *Annals of Oncology*, Volume 14, Issue 7, pp. 973–1005, Copyright © 2003 European Society for Medical Oncology, by permission of Oxford University Press.

A comprehensive strategy for cancer control might lead to the avoidance of a sizeable proportion of human cancers, and the greatest benefit can be achieved via tobacco control. However, such a strategy would imply major cultural, societal, and economic changes. More modest objectives for cancer prevention should focus on the neoplasms and the exposures that are prevalent in any given population. For example, vaccination of children against HBV is likely to be the most cost-effective cancer prevention action in many countries of Africa and Asia.

Neoplasms will continue to be a major source of human disease and death. Considerable efforts are made in the public and private domains to develop effective therapeutic approaches. Even if major discoveries in the clinical management of cancer patients will be accomplished in the near future, the changes will mainly affect the affluent part of the world population. Prevention of the known causes of cancer remains the most promising approach to reducing the consequences of cancer, in particular in countries with limited resources. Control of tobacco smoking and of smokeless tobacco products, moderation in alcohol intake, reduced overweight and obesity, increased physical activity, avoidance of exposure to solar radiation, control of known occupational carcinogens, and vaccination against known carcinogenic infectious agents are the main approaches.

Chronic obstructive pulmonary disease and asthma

Jeroen Douwes, Marike Boezen,
Collin Brooks, and Neil Pearce

Introduction to chronic obstructive pulmonary disease and asthma

The most common non-malignant respiratory conditions characterized by airway dysfunction are referred to collectively as obstructive airway diseases, and include chronic obstructive pulmonary disease (COPD) and asthma. Both conditions are highly prevalent and have increased dramatically in the past few decades, in Western and non-Western societies. They have a profound impact on quality of life for patients and their families, and COPD accounts for several million premature deaths per year worldwide (Lopez et al. 2006a).

COPD is usually defined as airflow obstruction due to inflammation of the peripheral airways and lung parenchyma, in which the airflow limitation is not fully reversible and progresses over time. Asthma is a heterogeneous chronic inflammatory disorder of the airways involving airflow limitation which is variable and reversible. Thus, the critical difference between both conditions is whether airflow obstruction is reversible. However, there is increasing evidence that reversibility of airflow obstruction may be observed in COPD, and that some asthmatics have irreversible obstruction. This has been described as ‘overlap syndrome’ (Gibson and Simpson 2009).

In this chapter we will describe both COPD and asthma in parallel. We first consider definitions, possible mechanisms, time trends, and population patterns of prevalence. Then we consider the evidence regarding risk factors for exacerbations as well as the initial development of both diseases.

Definitions

COPD

Traditionally COPD has been defined as irreversible airflow obstruction due to chronic bronchitis and emphysema which progresses over time (Petty 2006). Emphysema was already described in the seventeenth and eighteenth centuries (Petty 2006), and one of the first reports of chronic bronchitis as a serious and disabling disorder appeared in 1814 (Badham 1814). It was only a few years

later that Laënnec made the observation that chronic bronchitis and emphysema often occurred in the same subject at the same time (Laennec 1821; Petty 2002, 2006). However, it was not until about 150 years later that Burrows et al. (1966) suggested labelling the spectrum of chronic bronchitis and emphysema as ‘chronic obstructive lung disease’, or COPD. A few years previously, the Ciba Guest Symposium (Ciba Foundation Guest Symposium 1959) and the American Thoracic Society symposium (Committee on Diagnostic Standards for Nontuberculous Respiratory Diseases 1962) proposed the first definitions of chronic bronchitis and emphysema respectively. Current definitions are still largely based on these initial definitions, that is, chronic bronchitis is defined clinically as the presence of chronic productive cough for at least 3 consecutive months in 2 consecutive years; emphysema, on the other hand, is defined in pathological terms as an increase in the size of the distal airspaces and destruction of their walls without obvious fibrosis (American Thoracic Society Committee on Diagnostic Standards 1962).

The most recent definitions of COPD as reported in the American Thoracic Society (ATS), European Respiratory Society (ERS), and the Global Initiative for Chronic Obstructive Lung Disease (GOLD) guidelines (Rabe et al. 2007) emphasize the inflammatory response to noxious particles and gases as the predominant pathological feature of the disease, and have parted from the definition of COPD as being a syndrome of chronic bronchitis and emphysema. The widely accepted GOLD definition (Rabe et al. 2007) states that COPD is:

a preventable and treatable disease with some significant extrapulmonary effects that may contribute to the severity in individual patients. Its pulmonary component is characterised by airflow limitation that is not fully reversible. The airflow limitation is usually progressive and associated with an abnormal inflammatory response of the lung to noxious particles or gases. (Rabe et al. 2007)

Although no longer specifically included in the definition, it is still recognized that chronic bronchitis and emphysema are important causes of the chronic airflow limitation characteristic of COPD. The three main components (inflammation, airflow limitation that is not fully reversible, and a gradual loss of lung function over

time) represent the major pathophysiological events leading to the symptoms typically expressed by those with COPD: chronic and progressive cough, sputum production, and dyspnoea. Cough and sputum production may precede the development of airflow limitation, but fixed airflow obstruction may also develop without these symptoms (Petty 2006).

Clinical COPD

Spirometry is an essential tool in the clinical diagnosis of COPD and there are well accepted standardized guidelines (Miller et al. 2005). In COPD the maximum volume of air that can be forcibly expired (forced vital capacity (FVC)) is generally unaffected, or only marginally affected; however, the volume of air exhaled in the first second of expiration (forced expiratory volume in 1 second (FEV₁)) is significantly reduced. COPD is therefore defined based on the post-bronchodilator FEV₁/FVC ratio. A cut-point of 0.7 (i.e. 70 per cent) is widely used (Rabe et al. 2007), but this has not been clinically validated. Also, it is well recognized that using a fixed FEV₁/FVC ratio to define COPD independent of age has the potential for significant misclassification, with under-diagnosis in younger adults and over-diagnosis in the elderly (Medbo and Melbye 2007). Bronchodilator treatment prior to spirometry is important since it establishes whether obstruction is irreversible and distinguishes it from asthma in which obstruction is mostly reversible.

The degree of severity of COPD (defined as a FEV₁/FVC < 70 per cent) is usually based on the patient's FEV₁. The 2006 GOLD criteria classify COPD severity into four stages (Rabe et al. 2007) (see Box 8.3.1).

Recently these GOLD guidelines were revised, recognizing that although spirometry is still important for making a clinical diagnosis of COPD, it should be included as part of a combined assessment taking symptoms, spirometry, and history of exacerbations into account (Vestbo et al. 2012).

Despite the well-accepted guidelines for diagnosis, and the availability of inexpensive and convenient hand-held spirometers, COPD remains a significantly under-diagnosed disease particularly in younger people and women (Chapman et al. 2001; Watson et al. 2003; Halbert et al. 2006). This is largely because those with

mild COPD often have no symptoms, or they have symptoms that are not perceived by patients and healthcare providers as abnormal, therefore not warranting a spirometric assessment. Similarly, subjects may be less likely to be diagnosed with COPD if there is no history of smoking, one of the best-known risk factors for COPD.

Defining COPD in epidemiological surveys

In population-based surveys, COPD is often defined on the basis of: (1) self-report of a doctor diagnosis of COPD, bronchitis or emphysema; (2) self-report of respiratory symptoms; and (3) spirometry with or without prior bronchodilator treatment. It has repeatedly been shown that self-reports of a clinical diagnosis significantly underestimate the true disease prevalence (Chapman et al. 2006; Halbert et al. 2006). This is probably largely due to underdiagnosis of COPD by most general practitioners (see 'Clinical COPD').

Spirometric assessment to define COPD is therefore superior to a clinical assessment without spirometry, or a self-report of doctor-diagnosed COPD. However, the use of bronchodilators significantly complicates large population-based spirometry surveys, and many studies therefore do not collect post-bronchodilator measurements. The implications of failing to check for reversibility of airflow obstruction (using pre- and post-bronchodilator spirometry) may, however, result in an overestimation of the prevalence. For example, in a study in a random population sample of 2235 adults, the prevalence of COPD based on post-bronchodilator measurements was 7.0 per cent compared to 9.6 per cent for pre-bronchodilator measurements (Johannessen et al. 2005). Thus, the use of post-bronchodilator spirometry to determine the diagnosis of COPD in population-based studies is strongly recommended.

Asthma

The word 'asthma' comes from a Greek word meaning 'panting' (Keeney 1964), but reference to asthma-like symptoms can also be found in ancient Egyptian, Hebrew, and Indian medical writings (Ellul-Micallef 1976). There were clear observations of patients experiencing attacks of asthma in the second century, and evidence of disordered lung anatomy as far back as the seventeenth century (Willis 1678).

The definition of asthma initially proposed at the Ciba Foundation conference in 1959 (Ciba Foundation Guest Symposium 1959) and endorsed by the American Thoracic Society in 1962 (American Thoracic Society Committee on Diagnostic Standards 1962) is that 'asthma is a disease characterized by wide variation over short periods of time in resistance to flow in the airways of the lung'. Although these features receive lesser prominence in some current definitions, as the importance of airways inflammation is recognized, they are still integral to the current Global Initiative for Asthma (GINA) description of asthma as:

a chronic inflammatory disorder of the airways in which many cells and cellular elements play a role. The chronic inflammation is associated with airway hyperresponsiveness that leads to recurrent episodes of wheezing, breathlessness, chest tightness, and coughing, particularly at night or in the early morning. These episodes are usually associated with widespread, but variable, airflow obstruction within the lung that is often reversible either spontaneously or with treatment. (GINA 2006)

Box 8.3.1 GOLD criteria of COPD severity

- ◆ Stage I, mild: FEV₁ ≥ 80% predicted.
- ◆ Stage II, moderate: 50% ≤ FEV₁ < 80% predicted.
- ◆ Stage III, severe: 30% ≤ FEV₁ < 50% predicted.
- ◆ Stage IV, very severe: FEV₁ < 30% predicted *or* FEV₁ < 50% predicted *plus* chronic respiratory failure (i.e. arterial pressure of oxygen (PaO₂) < 8.0 kPa (60 mm Hg) with or without arterial pressure of CO₂ (PaCO₂) > 6.7 kPa (50 mm Hg)) while breathing air at sea level).

Reproduced with permission from Rabe, K.F. et al., Global strategy for the diagnosis, management, and prevention of chronic obstructive pulmonary disease: GOLD executive summary, *American Journal of Respiratory and Critical Care Medicine*, Volume 176, Number 6, pp. 532–55, Copyright © 2007 The American Thoracic Society, DOI: 10.1164/rccm.200703-456SO.

These three components—chronic airways inflammation, reversible airflow obstruction, and enhanced bronchial reactivity—therefore form the basis of current definitions of asthma. They also represent the major pathophysiological events leading to the symptoms of wheezing, breathlessness, chest tightness, cough, and sputum by which physicians clinically diagnose this disorder.

Clinical asthma

There is no single test or pathognomonic feature which defines the presence or absence of asthma. Furthermore, the variability of the condition means that evidence of it may or may not be present at assessment. Thus, a diagnosis of asthma is made on the basis of the clinical history, combined with physical examination and respiratory function tests over a period of time. Several studies have found the prevalence of physician-diagnosed asthma to be substantially lower than the prevalence of asthma symptoms in the community (e.g. Asher et al. 1998). This is not surprising since a clinical diagnosis of asthma can only be made if a person presents him- or herself to a doctor. This requires an initial self-assessment of the symptoms, as well as access to a doctor once a self-assessment has been made. Several further medical consultations may be required. Thus, diagnosed asthma is dependent not only on morbidity, but also on a patient's symptom perception, physician practice, and healthcare availability. Furthermore, there are several disorders which have signs and symptoms (such as wheeze) which can be confused with or mimic aspects of asthma, including COPD, dysfunctional breathing, eosinophilic bronchitis, vocal cord dysfunction, and bronchiectasis (King and Moores 2008).

There are, however, a number of tests that may facilitate the diagnosis and monitoring of asthma. Measurements of lung function are the most frequently used and provide important information on airflow variability, reversibility, and severity. Airflow limitation is generally measured using spirometry or a peak expiratory flow (PEF) meter. PEF meters are inexpensive and easy to use, but they are less precise than spirometry, and may underestimate the degree of airflow limitation (Aggarwal et al. 2006), therefore spirometry is preferred. Recent guidelines have emphasized the importance of conducting spirometry both before and after bronchodilator treatment when assessing lung function in asthma (Bateman et al. 2008). This is important since it establishes if obstruction is irreversible, and allows distinction from COPD. Reversibility of FEV₁ of ≥ 12 per cent and ≥ 200 mL from the pre-bronchodilator value is generally accepted as a valid indication of asthma (GINA 2006). However, due to the highly variable nature of the condition, repeated lung function tests are required, as some patients may not display reversibility when their asthma is well controlled (McCormack and Enright 2008). Moreover, although asthma is generally associated with reversible airflow obstruction, it has been estimated that between 35 and 50 per cent of asthmatics have at least some degree of irreversible obstruction (Bel 2004). Additionally, reversibility may be present in non-asthmatics (van Vugt et al. 2012).

In subjects with asthma symptoms but normal lung function, bronchial hyperresponsiveness (BHR) testing may be used as a diagnostic aid. BHR constitutes airway narrowing to non-specific stimuli, such as exercise, cold air, and chemical irritants, and can be measured as airway responsiveness to histamine, methacholine, adenosine-5'-monophosphate (AMP), hypertonic saline,

exercise challenge (de Meer et al. 2004a), and mannitol powder (Parkerson and Ledford 2011). However, although BHR is related to asthma, it may occur independently of asthma, and vice versa (Pearce et al. 2000a), which makes the BHR test of limited use for individual asthma diagnostics.

More recently an increasing number of tests are available to measure non-invasive markers of airway inflammation including sputum induction tests (Simpson et al. 2006), exhaled nitric oxide tests (Taylor et al. 2006) and measurements of inflammatory markers in exhaled breath condensate (Kharitonov and Barnes 2006). Whilst these tests may be useful in establishing asthma phenotypes (Douwes et al. 2002b; Simpson et al. 2006) and identifying patients who are more likely to respond to optimal treatment (Donohue and Jain 2013), they have as yet to be convincingly demonstrated to aid in asthma diagnosis, although it has been suggested that fractional exhaled nitric oxide measurements had a stronger asthma diagnostic capability (88 per cent sensitivity) than either peak flow or spirometric assessment (between 0 and 47 per cent sensitivity) (Smith et al. 2004).

There have been several approaches used to categorize asthma (Wenzel 2012). However, until recently, asthma has most commonly been clinically classified on the basis of severity using GINA criteria (GINA 2006), which subdivided asthma into four categories (intermittent, mild persistent, moderate persistent, and severe persistent). More recent guidelines (GINA 2013) have suggested that clinical categorization should be based on the current level of asthma control (controlled, partly controlled, and uncontrolled), which may more adequately address the individual clinical needs of the patient.

Overlap syndrome

Although reversibility of airway obstruction (or the lack thereof) is the primary clinical characteristic used to define either asthma or COPD, it is increasingly recognized that irreversible or only partially reversible airway obstruction may be observed in some asthmatics (Vonk et al. 2003), and conversely, some COPD patients may show a measurable degree of reversibility (Calverley et al. 2003). It is therefore difficult to clearly distinguish and diagnose the two conditions, particularly in older patients. This has led to the description of 'overlap syndrome', in which obstructive respiratory disease shows features of both asthma and COPD (Gibson and Simpson 2009). In fact, it has been previously suggested that COPD and asthma should not be considered as separate diseases, but rather as different expressions of the same disease entity. This theory, proposed in 1961 and known as the *Dutch hypothesis*, has since been heavily debated (Kraft 2006; Barnes 2006).

To date, there have been few epidemiological studies examining the incidence and prevalence of the overlap of COPD and asthma. However, it has been suggested that between 15 and 20 per cent of patients with obstructive airway diseases have evidence of overlap (Soriano et al. 2003), and this is most commonly seen in those with a history of smoking (Gibson and Simpson 2009).

Defining asthma in epidemiological surveys

Defining and diagnosing asthma in population-based epidemiological surveys poses even greater difficulties than defining asthma in individuals. Because of this, asthma prevalence surveys usually focus on self or parental-reported 'asthma symptoms' rather than diagnosed asthma (Burney et al. 1994; Asher et al.

1995). This approach allows a large number of participants to be rapidly surveyed without great cost. Of the symptoms clinically associated with asthma, epidemiological studies have shown that wheezing is the most important symptom for the identification of asthma, and thus the majority of questionnaires used to assess asthma prevalence are based on this symptom (Pearce et al. 1998).

An alternative approach to symptom questionnaires has been to use more 'objective' measures such as BHR testing, either alone or in combination with questionnaires. In particular, it has been suggested that asthma should be defined in epidemiological studies as symptomatic BHR (Toelle et al. 1992). However, some have criticized the use of BHR, and have questioned whether it is more valid than symptoms questionnaires (Pearce et al. 2000a). Furthermore, due to the variability of asthma, BHR may not be present at the time of assessment (Shaw et al. 2012).

Mechanisms, prevalence, and risk factors of COPD

Mechanisms of COPD

COPD encompasses emphysema, chronic bronchitis, or a combination of both conditions. Emphysema is characterized by loss of lung tissue elasticity and destruction of alveolar architecture. As a result of this the small airways collapse during exhalation, leading to air trapping and impaired ability to exhale. Chronic bronchitis involves inflammation of the airways, resulting in thick mucus which makes it difficult to efficiently inhale air into the lungs. In COPD, this airway inflammation is characterized by (non-allergic) T-helper 1 (TH₁)-associated CD8⁺ T cell and neutrophilic involvement (Chrysafakis et al. 2004; Simpson et al. 2013).

COPD is largely (but not exclusively) attributable to smoking. An exception is the genetically mediated alpha-1-antitrypsin (AAT) deficiency, where carriers need no environmental smoke exposure to develop COPD. However, AAT deficiency accounts for a minimal number of COPD cases worldwide (<1 per cent). Thus, the majority of COPD cases are due to smoking. Despite this, genetics also likely plays a role, as only a small proportion of smokers develop COPD. These 'susceptible smokers' show premature onset of lung function decline and, to a lesser extent, more rapid rates of decline later in life (Tager et al. 1988). In non-smokers, FEV₁ declines at a mean rate of approximately 30 mL/year during adult life, whereas in smokers, this is increased to 30–45 mL/year. Within a subset of susceptible cigarette smokers the rate of decline is 80–100 mL/year, and only 10–20 per cent of Caucasian chronic heavy cigarette smokers develop symptomatic COPD.

The deleterious effect of smoking is due to the fact that cigarette smoke contains a large amount of free radicals which disturbs the reduction/oxidation balance in the lungs, leading to elevated oxidative stress. Such an oxidant overdose can injure lung tissue directly by oxidation of cellular components, or indirectly by promoting neutrophilic inflammation and tissue degradation, subsequently affecting lung function (MacNee 2005; Kirkham and Rahman 2006).

Prevalence of COPD

COPD is a major global cause of mortality and morbidity, with exacerbations leading to frequent hospitalization. Despite the

large personal, societal, and economic burden (Rennard et al. 2002) only about 30 prevalence surveys of COPD had been reported until 2001 (Chapman et al. 2006). The establishment of the Burden Of Obstructive Lung Disease (BOLD) Initiative (see later), and other recent international initiatives to assess the global burden of COPD, allow more valid comparisons of the prevalence of COPD over time and across nations in the near future. Below, the most important studies currently available are summarized.

European epidemiological studies of COPD show prevalence estimates for COPD of 4–11 per cent (Vestbo 2004). These differences in prevalence estimates are presumed to be attributable to differences in risk exposures or population characteristics, but methods and definitions used to measure COPD may also play a role. Definitions of COPD used in these studies vary from a doctor's diagnosis of COPD, to more rigid definitions based on pathology and/or pulmonary lung function testing.

Halbert and co-workers (Halbert et al. 2006) assessed the reasons for conflicting prevalence estimates described in the literature. They selected studies that had: (1) estimated population-based COPD prevalences and (2) clearly described the methods used to obtain these estimates. In total, 32 studies presenting prevalence data for COPD were identified and reviewed, representing 17 countries and eight WHO regions. Prevalence estimates were based on spirometry (11 studies), respiratory symptoms (14 studies), patient-reported disease (10 studies), or expert opinion. The reported prevalence of COPD ranged from 0.23 to 18.3 per cent, with the lowest prevalences (0.2 to 2.5 per cent) being those based on expert opinion. Sixteen studies had measured rates that could confidently be extrapolated to an entire region or country. All of these 16 studies were conducted in Europe or North America, and in most the prevalence was between 4 per cent and 10 per cent. However, in some studies, COPD prevalence may be higher than this. For example, preliminary data from 13,301 participants in the LifeLines cohort study performed in the Netherlands showed that 1920 out of 13,301 subjects had GOLD stage I or higher (14 per cent) (i.e. 1402 had GOLD stage I, 494 GOLD stage II, and 24 GOLD stage III/IV).

Although the most accurate prevalence data are from Western countries, estimates suggest that about half of the approximately 2.7 million deaths in 2000 were in the Western Pacific Region, with the majority occurring in China. About 400,000 deaths occur each year from COPD in Western countries (Lopez et al. 2006b). Lopez and co-workers recently noted that the reported increase in global COPD deaths between 1990 and 2000 (0.5 million) is partially real, and partially due to better diagnostic methods and more extensive data availability in 2000. The regional COPD prevalence in adults in 2000 was estimated to vary from 0.5 per cent in parts of Africa to 3–4 per cent in North America (Soriano et al. 2000).

Halbert and co-workers (Halbert et al. 2006) quantified the global prevalence of COPD by performing a systematic review and random effects meta-analysis. For the 1990–2004 period they identified 101 prevalence estimates from 28 countries. The pooled prevalence of COPD was 7.6 per cent; the prevalence of chronic bronchitis alone was 6.4 per cent, and the prevalence of emphysema alone was 1.8 per cent. The pooled prevalence of COPD based on spirometry was 8.9 per cent.

The BOLD initiative developed standardized methods for estimating COPD prevalence and is currently one of only a few

studies with truly comparable international prevalence estimates (Buist et al. 2007). This study included 9425 participants from 12 centres in 12 countries including China, Turkey, Austria, South Africa, Iceland, Germany, Poland, Norway, Canada, the United States, Philippines, and Australia. Using identical methods, the study showed considerable variation in COPD prevalences, with GOLD stage II or higher COPD in women ranging from 5.1 per cent in Guangzhou, China, to 16.7 per cent in Cape Town, South Africa. In men it ranged from 8.5 per cent in Reykjavik, Iceland, to 22.2 per cent in Cape Town, South Africa. Using a similar study design, the Latin American Project for the Investigation of Obstructive Lung Diseases (PLATINO) studied the prevalence of COPD in 5315 study participants in five Latin American centres (Mexico, Venezuela, Brazil, Chile, and Uruguay) (Menezes et al. 2005). Crude prevalence rates of COPD ranged from 7.8 per cent in Mexico City, Mexico, to 19.7 per cent in Montevideo, Uruguay. Age and smoking did not fully explain the international variation in disease prevalence, suggesting a role for additional risk factors.

Although COPD is mainly observed in the elderly, it is not a disease of the elderly alone. In the Confronting COPD Study, the presence of COPD in younger age groups has also been described (Rennard et al. 2002); a phenomenon confirmed in the European Community Respiratory Health Survey, which verified COPD diagnosis using spirometric testing in random population samples of younger age (<45 years) (Vestbo 2004).

Future prevalence and burden of COPD

Assessing the future prevalence and burden of COPD requires the consideration of changing population distributions and smoking habits. For example, Feenstra and co-workers (Feenstra et al. 2001) in 2003 used a dynamic multistage life table model to compute projections for the Netherlands. Changes in population size and composition were predicted to cause COPD prevalence to increase from 21/1000 in 1994 to 33/1000 in 2015 for men, and from 10/1000 to 23/1000 for women. Changes in smoking behaviour would reduce the projected prevalence to 29/1000 for men, but would increase it to 25/1000 for women. The overall increases in COPD were estimated to be 43 per cent in men and 142 per cent in women.

Vestbo et al. examined survival after admission due to COPD in 267 men and 220 women who had participated in the Copenhagen City Health Study, and who were hospitalized with a discharge-diagnosis of COPD. The crude 5-year survival rate after a COPD admission was higher in women (52 per cent) than in men (37 per cent). However, estimations of the overall mortality due to COPD in the next decade showed that COPD mortality within women was expected to exceed that of men, with a similar trend observed in the United States. Thus, with the expected global increase in female mortality from COPD, mortality rates for females will soon equal or exceed those for males (Crockett et al. 1994; Mannino et al. 1997; Vestbo et al. 1998; Vestbo 2002; Watson et al. 2003).

Risk factors for COPD

In the past few decades, the environmental risk factors for COPD, that is, smoking, air pollution, occupational exposure, childhood respiratory illness, diet, and exposure to respiratory allergens, have been studied in detail. Also, the presence of respiratory symptoms, increased numbers of blood eosinophils, a family

history of asthma, and increased airway responsiveness were all found to be significant predictors of reduced level of FEV₁ (Wang et al. 2004; de Marco et al. 2013).

Cigarette smoking

The WHO has estimated that 73 per cent of all COPD mortality in high-income countries is caused by smoking; the estimate for low- and middle-income countries was 40 per cent (Lopez et al. 2006a). Tobacco smoke therefore is the most important cause of COPD. In fact, there is a well-established association between current and cumulative smoking and COPD, and several cohort studies have shown that adult smokers experience a faster FEV₁ decline than non-smokers. This excess decline in lung function may return to normal levels of ageing-related decline after smoking cessation (Camilli et al. 1987). Women and children are considered to be particularly sensitive to the effects of inhaled tobacco smoke (Xu et al. 1994) and significant reductions in FEV₁ due to environmental tobacco smoke among children with smoking parents have been shown (Tager et al. 1983).

What is most striking about the epidemiology of COPD has been the change in prevalence in women in the past decade (Lopez and Murray 1998). Due to increased smoking rates in women and women taking up smoking at younger ages in recent decades (Kemm 2001; Watson et al. 2003), the prevalence of COPD in women in the United Kingdom reached the same level as that of men in the previous decade (Lopez et al. 2006b). A similar pattern is seen in the United States, and this is expected to be reflected in other European countries in the near future (Halbert et al. 2003). Nonetheless, as noted earlier, women with COPD remain less likely to be diagnosed and treated (Miravitlles et al. 2005). General practitioners, in particular, consider the diagnosis of COPD less frequently in women than in men presenting with the same risk factors and clinical symptoms (Miravitlles et al. 2006).

Few data are available on the incidence of COPD according to smoking habits. Analysis of the Copenhagen City Heart Study confirmed a higher incidence of COPD in smokers than non-smokers, with 27 per cent of participants who continued to smoke over a 25-year period developing COPD as defined by GOLD stage II–IV COPD, compared with 5.7 per cent of non-smokers (Lokke et al. 2006). The longitudinal Vlagtwedde/Vlaardingen Cohort Study (with a follow-up of 25 years) also showed that persistent cigarette smokers (odds ratio (OR) = 1.99, 95 per cent confidence interval (CI) = 1.68–2.35), recidivist smokers (OR = 1.96, 95 per cent CI = 1.34–2.86), variable pipe/cigar smokers (OR = 2.11, 95 per cent CI = 1.52–2.91), and subjects who stopped smoking (OR = 1.39, 95 per cent CI = 1.08–1.80) had an increased risk of developing COPD compared to never smokers. The risks of developing COPD in sustained ex-smokers (OR = 0.98, 95 per cent CI = 0.79–1.22), starters (OR = 1.62, 95 per cent CI = 0.87–2.99), brief smokers (OR = 1.22, 95 per cent CI = 0.76–1.94) and persistent pipe/cigar smokers (OR = 1.41, 95 per cent CI = 0.98–2.04) were not significantly different. Therefore, it was concluded that, taking longitudinal smoking habits into account, subjects who quit smoking between two successive surveys still had an increased risk of developing COPD compared with never smokers, whereas sustained ex-smokers were no longer at risk of developing COPD.

Other environmental risk factors

Although cigarette smoking is considered to be the main risk factor for COPD development, recent estimations are that 25–45

per cent of COPD patients have never smoked (Salvi and Barnes 2009). Some of these never-smoking COPD patients may have previously been diagnosed with asthma, as a history of asthma has been shown to be a risk factor for COPD in some studies (Silva et al. 2004). However, other environmental exposures (e.g. occupational exposures and air pollution) are also important risk factors, specifically in non-Westernized countries.

Occupational exposure to dusts, gases, and fumes have been shown to be associated with the rate of decline in FEV₁ and the development of COPD. In fact, an ad hoc committee of the American Thoracic Society that reviewed occupational studies on COPD estimated that 15–20 per cent of COPD was caused by occupational factors (Balmes 2005), and other studies suggest that these estimates could even be higher. For example, analyses of data collected in the Third National Health and Nutrition Examination Survey in the United States suggest that approximately 20 per cent of COPD cases in the United States are attributable to work-related exposures (Hnizdo et al. 2002). The proportion was even higher (approximately 30 per cent) in never smokers. Combined exposures to smoking and occupational factors have been shown to have greater than additive effects (Trupin et al. 2003). Some examples of occupational risk factors for COPD are coal dust, silica dust, oil mists, welding fumes, and organic dusts including cotton, grain, and wood (Balmes 2005).

Indoor air pollutants are another important risk factor for COPD, particularly in low-income countries where biomass fuels (wood and crop residues) and coal fuels are often used for heating and cooking without appropriate ventilation (Liu et al. 2007). WHO estimates suggest that indoor smoke from biomass fuels may cause 35 per cent of all COPD cases in low- and middle-income countries (Lopez et al. 2006a). COPD is also related to outdoor pollution levels, but the attributable risk is expected to be relatively small (Tashkin et al. 1994).

Genetic risk factors

Since COPD is predominantly expressed in later years, genetic factors are difficult to study, as the parents of individuals with COPD have often already died, and the children of subjects with COPD are likely to be too young to have significant fixed airway obstruction (van Diemen and Boezen 2007). Initial genetic studies on COPD included small numbers of subjects and applied different definitions of disease, hampering a valid comparison between studies and increasing the likelihood of spurious results. Many positive results from genetic studies of COPD have therefore not been replicated (Boezen and Postma 2007). Furthermore, lack of replication might also be due to the apparent difficulties of extrapolating results from one population to another, such as Asians and Caucasians, as a result of lower prevalences of particular polymorphisms in Caucasians (Boezen and Postma 2007).

More recently, several large population-based cohort studies have been conducted in which excess decline in lung function leading to development of COPD was studied prospectively. Such studies may allow assessment of different mechanisms that can lead to poor lung function. For example, subjects may have experienced an unusually high rate of decline in lung function, may not have attained the normal maximal level of lung function, or the age of onset of decline may have been unusually early. Genetic factors may affect any one, or a combination, of these different patterns of lung function loss. Therefore, it is of importance to study

the genetic contribution to lung function loss using a longitudinal study design, covering the time span during which these different patterns and their underlying causes evolve (van Diemen and Boezen 2007).

Candidate gene studies on COPD

Most studies on genetics of COPD have focused on genes that are involved in the processing of various tobacco smoke products, oxidative stress, or in the protease/antiprotease balance. In particular, variations in the genes encoding enzymes that detoxify cigarette smoke products (and are thus protective against oxidative stress) may explain why only a proportion of smokers develop COPD.

Candidate genes identified in this way include *EPHX1*, *ADAM33*, *MMP1*, *GSTP1*, *GSTT1*, *GSTM1*, *HMOX1*, and *SERPINA1* (Postma et al. 2011). However, two recent meta-analyses showed that there are only a few genes with statistically significant associations with COPD, namely: *GSTM1*, *TGFB1*, *TNF*, *SOD3*, *IL1RN*, *VNTR*, *TNFA*, *GSTP1*, and *EPHX1* (Smolonska et al. 2009; Castaldi et al. 2010). Of interest, these genes are positioned in biologically plausible pathways of oxidative stress response and defence against oxidative stress, like *GSTM1*, *TGFB1*, *TNF*, *SOD3*, *TNFA*, *GSTP1*, and *EPHX1* (Postma et al. 2011).

Genome-wide association studies on COPD

Genome-wide association (GWA) studies are applied to identify genetic loci that are associated with disease using markers throughout the genome, rather than selected on the basis of their assumed biological function (Boezen 2009). Using GWA study approaches, several novel loci have now been identified for COPD.

The first COPD GWA study identified variants in the nicotinic acetylcholine receptor (nAChR) subunit genes, *CHRNA3/5* (Pillai et al. 2009) and this was confirmed in later studies (Wilk et al. 2012). SNPs in this nicotinic cluster have previously been related to smoking habits and addiction. Another recent GWA study identified a new locus on chromosome 19q13 which was associated with COPD and severe COPD. This region includes *RAB4B*, *EGLN2*, *MIA*, and *CYP2A6*, and has previously also been identified in association with cigarette smoking behavior (Cho et al. 2012). The identification of loci involved in smoking habits and smoking addiction have triggered some discussion whether these genes are directly involved in lung function loss leading to COPD per se, or indirectly through the effects of nicotine addiction (Budulac et al. 2012).

Other recent GWA studies showed associations between several loci and reduced FEV₁ and FEV₁/FVC ratio, some of which indicated developmental genes like *HHIP* (Hancock et al. 2010).

Mechanisms, prevalence, and risk factors of asthma

Until recently, asthma was widely regarded as an allergic disease involving IL-5-mediated eosinophilic airways inflammation (Douwes et al. 2002b). As a consequence, asthma is often grouped together with other 'allergic diseases' such as rhinitis and eczema. This assumption has, however, been challenged (Pearce et al. 1999; Ronchetti et al. 2007; Weinmayr et al. 2007), and it is now increasingly accepted that asthma is a heterogeneous syndrome that may be associated with different types of inflammation (Wenzel 2012). In

particular, there has been growing interest in other non-allergic/non-eosinophilic mechanisms underlying asthma (Douwes et al. 2002b; Simpson et al. 2007).

Allergic asthma

Allergic asthma is caused by IgE-mediated (or atopic) inflammatory mechanisms in which a large number of cells play a role including mast cells, eosinophils, T-lymphocytes, dendritic cells, and macrophages. Briefly, the sensitization process involves the interaction of allergens with dendritic cells in the airway mucosa, which subsequently migrate to the regional lymph nodes, where allergen epitopes are presented to B and T cells. This results (through T-helper-2 (Th₂) responses) in the production of allergen-specific IgE. Once allergic, a subject can develop symptoms minutes after being exposed, which is known as the early-phase allergic reaction. In the early phase, symptoms are a result of allergen-IgE antibody cross-linking at the surface of the mast cells, leading to degranulation and release of vasoactive and inflammatory mediators, causing contraction of bronchial smooth muscle and oedema in the airways. Clinically this results in a decreased lung function and symptoms of wheeze, shortness of breath, chest tightness, and coughing.

During the late phase of the allergic reaction (4–8 hours after exposure), eosinophil-related inflammatory reactions are particularly important. A critical step in this late phase reaction is the activation of Th₂ cells, which release several pro-inflammatory cytokines including IL-5, resulting in the influx and activation of eosinophils. This reaction is characterized by the development of a non-specific BHR that can continue for several days. Repeated exposures may result in more permanent BHR.

Non-allergic asthma

A systematic review of population-based studies (Pearce et al. 1999) found that the proportion of asthma cases that are attributable to atopy is usually less than half (Table 8.3.1). Standardized comparisons across populations or time periods also show only weak and inconsistent associations between the prevalence of asthma and the prevalence of atopy (Priftanji et al. 2001). For example, the International Study on Allergies and Asthma in Children (ISAAC; see later) showed that the association between atopy and asthma symptoms differed strongly among populations, but increased with economic development (Weinmayr et al. 2007). In this study, the fraction of current wheeze attributable

to atopy ranged from 0 per cent in Ankara (Turkey) to 93.8 per cent in Guangzhou (China) (Fig. 8.3.1); the overall proportion of asthma cases that were attributable to atopy was only 40.7 per cent in affluent countries and 20.3 per cent in non-affluent countries. The European Community Respiratory Health Survey (see later) showed that asthma attributable to atopy in adults ranged from 4 to 61 per cent between individual study centres with an overall estimate of only 30 per cent for all centres combined (Sunyer et al. 2004).

Several studies have also shown that patients may have severe and persistent asthma in the absence of eosinophilic inflammation, and may experience an exacerbation of asthma without an increase in eosinophilic inflammation (Turner et al. 1995). Furthermore, recent studies have demonstrated that less than 50 per cent of asthma cases are attributable to eosinophilic airway inflammation, the hallmark of allergic asthma (Douwes et al. 2002a; Simpson et al. 2006).

Thus, evidence from studies of eosinophilia and asthma is consistent with that from studies of atopy and asthma: in both instances, at most about one-half of asthma cases appear to be due to 'allergic' mechanisms.

The underlying mechanisms of non-eosinophilic/non-allergic asthma have yet to be fully elucidated. Some studies suggest that it may involve innate-like pathology, with increased airway neutrophil influx and expression of innate receptors such as Toll-like receptors (Simpson et al. 2007). There is also some evidence for combined activation of both innate (neutrophils) and allergic (eosinophils) inflammatory mechanisms in asthma. This has led to suggestions that asthma can be characterized into four inflammatory subtypes on the basis of sputum eosinophil and neutrophil proportions: eosinophilic asthma, neutrophilic asthma, mixed granulocytic asthma, and paucigranulocytic asthma (Simpson et al. 2006) (Fig. 8.3.2).

The pathophysiological mechanisms involved in paucigranulocytic asthma are not clear, but it is possible that they may involve remodelling rather than active inflammation (Holgate 2012).

There have been contradictory findings reported regarding the clinical characteristics of eosinophilic asthma (EA) and non-eosinophilic asthma (NEA) in adults. Some studies have shown eosinophilic airway inflammation in adult asthma in association with increased symptom severity and frequency (Gibson et al. 2000; Jatakanon et al. 2000). Despite this, NEA has been observed across the spectrum of clinical severity (Pavord et al. 1999; Wenzel et al. 1999), and several studies have shown very few clinical differences between EA and NEA (Simpson et al. 2006; Berry et al. 2007). However, there are also distinct differences: in particular, non-eosinophilic asthmatics appear less atopic, have normal subepithelial layer thickness, and perhaps most importantly, they have a poor short-term response to treatment with inhaled corticosteroids (Berry et al. 2007). NEA is also more likely to be associated with smoking history (Chalmers et al. 2001) and obesity (Sutherland et al. 2009). Thus, despite some clinical similarities, eosinophilic and non-eosinophilic asthma appear to represent distinct pathological phenotypes.

Asthma time trends

It has long been suspected that the prevalence of asthma has been increasing not only in industrialized countries, but also in developing countries (Pearce et al. 2000b). However, this has been a

Table 8.3.1 Summary of nine population-based studies in children and seven population-based studies in adults: proportions of asthmatics and non-asthmatics who are atopic and % of asthma cases attributable to atopy

Age-group	% Non-atopic	% atopic	Pooled relative risk	% cases attributable to atopy
Children	29	58	3.4	38
Adults	24	54	3.7	37

particularly difficult issue to resolve because of the lack of systematic standardized studies measuring changes in asthma prevalence over time, with some reviewers arguing that the increases in reported prevalence are largely due to increased awareness and diagnosis of asthma symptoms (Magnus and Jaakkola 1997). Nevertheless, most studies which have determined the prevalence of asthma symptoms using the same methodology in the same community at different times, have reported that asthma prevalence has increased in recent decades, and that the magnitude of the increase has in some cases been substantial (Table 8.3.2).

One of the most informative studies to date is that of Haahtela et al. (1990) who analysed the medical examination reports of

approximately 900,000 conscripts to the Finnish defence forces during 1966–1989, and a proportion of those examined in 1926–1961. During 1926–1961 the prevalence of asthma recorded at call-up examinations was in the range of 0.02 per cent to 0.08 per cent. However, asthma prevalence increased from 0.29 per cent in 1966 to 1.79 per cent in 1989. The authors concluded that the increase was unlikely to be simply due to improved diagnostic methods. This conclusion was strengthened by a concomitant rise (from 0.12 per cent in 1966 to 0.75 per cent in 1989) in exemptions and discharges due to asthma. This study is consistent with other evidence showing that the increases in asthma prevalence in industrialized countries appear to have

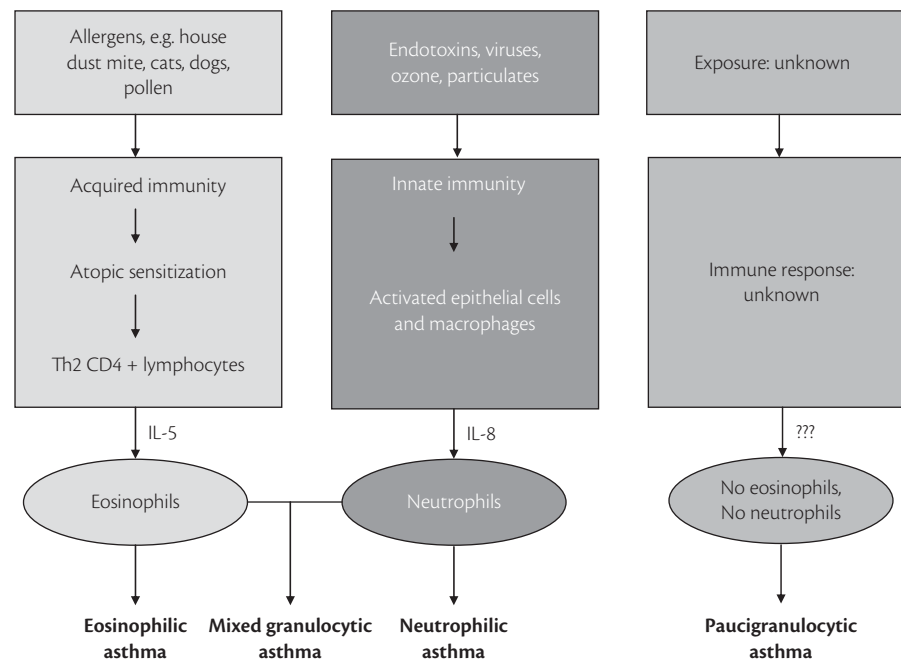

Fig. 8.3.2 The inflammatory pathways of various asthma phenotypes.

commenced after the Second World War, particularly in the 1960s and 1970s (Table 8.3.2).

However, several recent studies in affluent countries have reported either no increase, or even a decrease, in asthma prevalence over the last decade. For instance, Bollag et al. (2005) found that overall consultations for asthma in primary care in Switzerland increased from 1989 to 1994, then stabilized, and have declined since 2000. The observation that asthma incidence might be falling is in agreement with several other studies showing similar time trends for asthma and hay fever (Pearce and Douwes 2005).

International prevalence comparisons

The causes of the international time trends in the prevalence of asthma are unclear, and are currently under intensive investigation. An important component of this research process involves the use of standardized international prevalence comparisons (Pearce et al. 1998), which involve the compilation of information from large numbers of people in random samples collected in a comparable manner across social groups, regions, and countries. This approach has been used in the international survey of asthma prevalence in adults (Burney et al. 1994), and in the International Study of Asthma and Allergies in Childhood (Pearce et al. 1993; Asher et al. 1995; Ellwood et al. 2005).

The European Community Respiratory Health Survey

In each centre of the European Community Respiratory Health Survey (ECRHS), a representative sample of 3000 adults, aged 20–44 years, completed a Phase I screening questionnaire assessing asthma symptoms and medication use (Burney et al. 1994). Individuals answering ‘yes’ to waking with an attack of shortness of breath, an attack of asthma or current asthma medications were defined as ‘asthmatic’. A random subsample of 600 subjects and an additional sample of up to 150 ‘asthmatic’ individuals were then

studied in more detail in Phase II, with measurements of skin prick tests to common allergens, serum total and specific IgE, bronchial responsiveness to inhaled methacholine, as well as an additional questionnaire on asthma symptoms and medical history, occupation and social status, smoking, the home environment and the use of medications and medical services. The Phase I results (Burney et al. 1996) included data from 48 centres, predominantly in Western Europe, with only nine centres from six countries (Algeria, Iceland, India, New Zealand, Australia, and the United States) outside of Europe. Phase II was conducted in 37 centres in 16 countries (Burney et al. 1996).

The International Study of Asthma and Allergies in Childhood

The International Study of Asthma and Allergies in Childhood (ISAAC) (Asher et al. 1995; Ellwood et al. 2005) had a similar study design, with a simple Phase I survey and a more in-depth Phase II survey. However, in order to obtain the maximum possible participation across the world, Phase I (which was conducted in 155 centres in 56 countries) was separated from Phase II (which was conducted in a smaller number of centres), and the Phase I questionnaire modules were designed to be simple and inexpensive to administer. In addition, a video presentation of clinical signs and symptoms of asthma was developed (Shaw et al. 1995) in order to minimize translation problems. The population of interest was schoolchildren aged 6–7 years and 13–14 years. ISAAC Phase II was conducted by 30 centres in 22 countries and involved parental questionnaires ($n = 54,439$), skin prick tests ($n = 31,759$) and serum IgE measurements ($n = 8951$). House dust samples to measure indoor allergens were also collected (Weinmayr et al. 2007). Phase III involved a repeat of the phase I survey after an interval of 5–10 years in 106 centres in 56 countries in children aged 13–14 years ($n = 304,679$) and in 66 centres in 37 countries in children aged 6–7 years ($n = 193,404$) (Asher et al. 2006; Pearce et al. 2007).

Table 8.3.2 Changes in asthma prevalence in children and young adults

Country	Asthma prevalence			
	Period	1st study	2nd study	Reference
Australia	1964–1990	19.1%	46.0%	(Robertson et al. 1991)

What do the ECRHS and ISAAC studies show?

Firstly, both studies show striking international differences in asthma symptom prevalence with a particularly high prevalence of reported asthma symptoms in English-speaking countries (Fig. 8.3.3), that is, the British Isles, New Zealand, Australia, the United States, and Canada (Burney et al. 1996; Asher et al. 1998; Beasley et al. 1998). This appears to be unlikely to be entirely due to translation problems, since the same pattern was observed with the ISAAC video questionnaire (Asher et al. 1998).

Secondly, the ISAAC survey showed that centres in Latin America also had particularly high symptom prevalence (Fig. 8.3.3). This finding is of particular interest in that the Spanish-speaking centres of Latin America showed higher prevalences than Spain itself, in contrast to the general tendency for more affluent countries to have higher prevalence rates.

Thirdly, amongst the non-English-speaking European countries, both studies show high asthma prevalence in Western Europe, with lower prevalences in Eastern and Southern Europe. For example, in the ISAAC survey, there is a clear Northwest–Southeast gradient within Europe, with the highest prevalence being in the United Kingdom, and some of the lowest prevalences in Albania and Greece (Asher et al. 1998). The West–East gradient was particularly strong; in particular there was a significantly lower prevalence in the former East Germany than in the former West Germany.

Fourthly, Africa and Asia generally showed relatively low asthma prevalence (Fig. 8.3.3). In particular, prevalence was low in developing countries such as China and Indonesia whereas more affluent Asian countries such as Singapore and Japan showed relatively high asthma prevalence rates. Perhaps the most striking contrast is between Hong Kong and Guangzhou which are close geographically, and involve the same language and predominant ethnic group; Hong Kong (the more affluent city) had a 12-month period prevalence of wheeze of 12.4 per cent, compared with 3.4 per cent in Guangzhou (the less affluent city).

Fifthly, in contrast to the asthma findings, the highest prevalences of rhinitis symptoms were reported from centres scattered throughout most regions of the world, including Western Europe, Africa, North America, and South East Asia. Thus, although the prevalences of these conditions were correlated, the association was not particularly strong, suggesting that the major risk factors are different for these related disorders, or that they involve different latency periods and time trends.

Sixthly, the ISAAC Phase II study showed that the link between atopic sensitization and asthma symptoms differed strongly between populations and increased with economic development (Weinmayr et al. 2007); the association between atopy and flexural eczema was also weak and positively linked to gross national income (Flohr et al. 2008).

Finally, the asthma prevalence in many affluent countries has peaked or even begun to decline, whereas asthma symptom

Fig. 8.3.3 Wheeze in the previous 12 months for each centre by country ordered according to the mean prevalence for all centres in the country. Source: data from ISAAC Steering Committee, Worldwide variations in the prevalence of asthma symptoms: the International Study of Asthma and Allergies in Childhood (ISAAC), *The European Respiratory Journal*, Volume 12, Issue 2, pp. 315–35, Copyright © ERS Journals Ltd 1998.

prevalence continues to rise in less affluent countries. In particular, ISAAC Phase III showed that international differences in asthma symptom prevalence have reduced, particularly in 13–14-year-olds, with decreases in prevalence in English speaking countries and Western Europe and increases in prevalence in regions where

prevalence was previously low including Africa, Latin America, and parts of Asia (Fig. 8.3.4) (Asher et al. 2006; Pearce et al. 2007). Similarly, Phase II of the ECRHS found no further increase in current or severe asthma symptoms (Chinn et al. 2004). Nonetheless, a significant increase in diagnosed asthma was observed which most

Fig. 8.3.4 Ranking plot showing the change per year in prevalence of current wheeze (wheeze in the last 12 months) in 13–14-year-old children for each centre by country, with countries ordered by their average prevalence (for all centres combined) across Phase I and Phase III (the plot also shows the confidence interval about zero change for a given level of prevalence (i.e. the average prevalence across Phase I and Phase III) given a sample size of 3000 and no cluster sampling effect).

likely reflects changes in diagnostic labelling and/or medical treatment for mild and/or moderate asthma (Weiland and Pearce 2004).

Risk factors for asthma

These striking findings from the ISAAC and ECRHS surveys, together with recent studies within Western countries, are challenging established theories of the development of asthma, and facilitating the search for new theoretical paradigms. In this section we review evidence on traditional risk factors as well as some more recently suggested risk factors for asthma.

Atopy

As noted earlier, atopy is strongly associated with asthma within populations. However, the proportion of asthma cases that are

attributable to atopy is usually less than one-half (Pearce et al. 1999) and an even lower population attributable risk (~20 per cent) was found in less affluent populations (Weinmayr et al. 2007). Also, comparisons across populations suggest that the association between atopy and asthma is relatively weak and highly variable between populations (Sunyer et al. 2004; Weinmayr et al. 2007). Furthermore, although atopy may be a risk factor for asthma, it is not a classic environmental 'exposure' (e.g. indoor allergen exposure, smoking, air pollution) which could by itself explain increases in asthma prevalence. Rather it represents a biological response to various exposures (e.g. allergen exposure) which is modified by susceptibility factors (genetic and/or environmental).

Genetic factors

The heritable component of asthma has been variously estimated to be between 35 and 95 per cent (Ober and Yao 2011). However, asthma is multifactorial in origin and influenced by multiple genes and environmental factors. Thus, it is not inherited in a simple Mendelian fashion, and particular genetic factors may affect one or more aspects of the complex aetiological processes potentially involved in asthma including atopic sensitization, BHR, airway inflammation, and innate immunity. Investigating possible genes for these individual aetiological factors is also fraught with difficulties, as control of these factors is also multifactorial (Zamel et al. 1996). Another issue is that asthma development, exacerbations and progression may all involve different environmental triggers and genetic factors.

Despite the considerable heterogeneity observed, a number of genome linkage and GWA studies have identified several chromosomal regions significantly associated with asthma susceptibility. Regions with the strongest evidence include chromosome 2q, 5q, 6q, 11q, 12q, and 13q (Bierbaum and Heinzmann 2007). A more recent GWA study of 10,365 physician-diagnosed asthmatics supported some of these associations, and also provided evidence of asthma susceptibility linkage with chromosomes 8, 15, and 22 (Moffatt et al. 2010). From these studies, a large number of asthma-susceptibility candidate genes have been implicated, with only some confirmed in subsequent independent studies (Todd et al. 2011). These include *IL4*, *IL13*, *CD14*, and *ADRB2* on chromosome 5; *HLA-DRB1*, *HLA-DBQ1*, and *TNF* on chromosome 6; *IL33* on chromosome 9; *FCER1B* on chromosome 11; *SMAD3* on chromosome 15; *IL4RA* on chromosome 16; *ORMDL3/GSDMB* on 17q21; and *ADAM33* on chromosome 20 (Bierbaum and Heinzmann 2007; Moffatt et al. 2010). In many cases, the involvement of the products of these genes in asthma pathophysiology is feasible, as they are associated with a variety of inflammatory or epithelial/cell-contact pathways. However, in the GWA studies described, these genes make only a small contribution to overall disease risk on an individual basis, and there may be issues due to the use of different asthma classifications in different studies (Todd et al. 2011). Furthermore, some gene variants may only be associated with certain asthma subtypes, such as that observed between *ORMDL3/GSDMB* and childhood-onset asthma (Moffatt et al. 2010).

Demographic factors

There are a variety of demographic factors which are associated with asthma including age, gender (Anderson et al. 1992), and ethnicity (Pattemore et al. 2004).

Asthma incidence and prevalence are consistently lower in females than in males before age 12 years, whereas during adolescence and adulthood there is evidence of higher incidence and prevalence in females (Kimbell-Dunn et al. 1999). The reasons for this are unclear, but could be related to later age of asthma onset in childhood and adolescence in females and differences between boys and girls in exposures, airway size, and frequency and severity of lower respiratory tract illnesses. On the other hand, these differences could be due to hormonal influences on allergic predisposition, airway size, inflammation, and smooth muscle vascular functions (Redline and Gold 1994). Premenstrual asthma may be especially relevant to the hormonal involvement of asthma since it may not only cause asthma exacerbations but may thereby

affect the frequency and duration of asthma symptoms, resulting in an increase in the prevalence of 'current asthma'.

Studies in the 1960s and 1970s suggested that asthma is more common in children in the higher social classes. There has been less evidence of social class differences as the diagnosis of asthma has become more widespread (Littlejohns and Macdonald 1993), even though diagnostic labelling of wheezing in adults differs by social class (Littlejohns et al. 1989). However, severe asthma appears to be more common in children in the lower social classes (Stewart et al. 2001) and in some disadvantaged ethnic groups (Pattemore et al. 2004), and low socioeconomic status is associated with hospital admissions for asthma (Watson et al. 1996) and with reduced lung function in adults. This could represent either a greater prevalence of asthma in disadvantaged groups, or increased severity due to environmental factors (e.g. second hand tobacco smoke (SHS), nutrition, occupational exposures) (Eagan et al. 2002; Ellison-Loschmann et al. 2007) or inadequate disease management and poor access to healthcare (Ellison-Loschmann and Pearce 2006).

Obesity

Studies have shown an association between body weight and asthma in both adults and children, and prospective studies suggest that obesity precedes asthma (Ronmark et al. 2005; Noal et al. 2011). However, findings supporting this have not been entirely consistent (Noal et al. 2011). The evidence linking obesity and atopy is also conflicting with some studies suggesting that obesity is associated with asthma independent of atopy (Loerbroeks et al. 2008; Visness et al. 2010).

Diet

Many studies including several infant cohort studies have investigated the effects of breastfeeding on allergies and asthma with some studies showing protective effects, some showing no effect, and others suggesting that breastfeeding is a risk factor (Friedman and Zeiger 2005; Kramer et al. 2007; Matheson et al. 2007).

Other nutritional factors may also play a role in the aetiology of asthma. In particular, it has been speculated that the increase in asthma prevalence may be due to a change in dietary patterns in the past few decades, that is, as cultures have become more 'Westernized' they have shifted from growing and consuming locally grown foods to consuming more processed foods, as well as a reduction in the intake of fresh produce. This is supported by results from the ISAAC Phase II and other studies (Chatzi and Kogevinas 2009; Nagel et al. 2010), which found that fruit, vegetable, and fish consumption was associated with a lower prevalence of current wheeze and asthma. Trans-fatty acids and burger consumption, on the other hand may be associated with an increased risk (Asher et al. 2010). Some studies have found that development of some atopic disorders was associated with exposures to n-6 versus n-3 fatty acids, but this finding was not consistent for all atopy/allergies (Almqvist et al. 2007; Notenboom et al. 2011). Maternal folate supplementation during pregnancy has also been suggested as a risk factor for asthma in childhood.

Vitamin D

There is an increasing number of studies suggesting an association between vitamin D and asthma with several studies based on dietary questionnaire findings showing a protective effect of higher levels of maternal vitamin D on the development of asthma in

children (Muehleisen and Gallo 2013). In a recent study in which vitamin D levels were measured in cord blood, a similar protective effect of vitamin D was found with an inverse association with wheezing at the age of 15 months, 3 years and 5 years, but not for incident asthma by the age of 5 years (Camargo et al. 2011). Low serum vitamin D levels in asthmatic children and adults have also been associated with asthma severity and poor asthma control (Majak et al. 2011; Korn et al. 2013). However, the evidence has been mixed with some studies showing that infant vitamin D supplementation may be associated with an increased risk of atopy and allergic rhinitis in adulthood (Hypponen et al. 2004) and high maternal vitamin D levels with an increased risk of atopic eczema and asthma in children (Gale et al. 2008).

Outdoor air pollution

The role of outdoor air pollutants (particulate matter, ozone, nitrogen dioxide, and sulphur dioxide) in asthma has been extensively studied. An association between measures of distance to major roads or traffic density and asthma symptoms has been demonstrated in a number of European countries (World Health Organization 2005). Also, a large number of studies have reported associations between direct measurements of air pollution levels and exacerbation of pre-existing asthma, both in children and adults (Boezen et al. 1999; World Health Organization 2005). Some studies, including a birth cohort study (Brauer et al. 2007), have also suggested that air pollution may cause *new onset* of asthma and allergic disease. In particular, several large prospective studies have suggested a role for ozone (McDonnell et al. 1999; McConnell et al. 2002), although significant associations with some asthma outcomes were also shown for PM_{2.5}, soot, and NO₂ (Brauer et al. 2007).

Tobacco

The evidence for a role of tobacco smoke in asthma is strongest for increases in severity in children who already have asthma. However, an increasing number of studies also show positive associations between SHS and the initial occurrence of asthma (incidence) (Accordini et al. 2012). Earlier reviews and meta-analyses differed in their conclusions about the role of SHS (US EPA 1992; Office of Environmental Health Hazard Assessment 1997; US DHHS 2006; Strachan and Cook 1998), but a more recent meta-analysis including studies published between 1970 and 2005 concluded that household SHS exposure was positively and consistently associated with the incidence of new onset asthma (Vork et al. 2007) not only in younger, but also older children. A subsequent review and meta-analysis confirmed this conclusion, and suggested that SHS may increase the incidence of wheeze and asthma in children and young people by at least 20 per cent (Burke et al. 2012). Thus, despite some conflicting data (Eagan et al. 2002; Accordini et al. 2012), it generally appears that SHS causes new-onset asthma in children, and active smoking is causing asthma exacerbations, but may also be involved in the development of asthma itself in adolescents and adults.

Indoor air pollution

Little is currently known about the contribution of indoor air pollutants (other than SHS) to the incidence and prevalence of asthma. Nitrogen dioxide from burning fossil fuels has received the most attention while sulphur dioxide from burning sulphur-containing coal or gas, mosquito coil smoke, and formaldehyde from wood

preparation have also been considered. Particulates from open or closed wood and coal burning fires have received less attention in developed countries, but have been studied in developing countries where very high indoor levels have been encountered. Damp indoor environments and indoor fungal exposure may also play a role as demonstrated in a large number of studies conducted across many geographical regions (Douwes and Pearce 2003), with a 2011 report concluding that there is sufficient evidence for an association between indoor dampness and asthma development (Mendell et al. 2011).

Occupational exposures

Occupational asthma is the most common occupational respiratory disease in developed countries. For example, asthma accounted for 28 per cent of cases reported to the United Kingdom Surveillance of Work-related and Occupational Respiratory Diseases (SWORD) project (Meredith et al. 1991). Estimates of the total proportion of adult asthma which is thought to be occupational in origin range from 2 to 15 per cent in the United States, 15 per cent in Japan (Chan-Yeung and Malo 1994), 5 per cent in Spain (Kogevinas et al. 1996), 2–3 per cent in New Zealand (Fishwick et al. 1997), and 2–6 per cent in the United Kingdom (Meredith and Nordman 1996). A recent study in the United States estimated that new-onset asthma may be caused by occupational exposures in as many as one of six adult patients (Mazurek et al. 2013). More than 250 agents have been identified as causes of occupational asthma (State of New Jersey Department of Health (n.d.)). Some of the most common occupational asthmagens include flour/grain dusts, wood dusts, latex allergens, and isocyanates.

Respiratory viral infections

Viral infections are common causes of exacerbations of asthma, and associated with hospital admissions in both children and adults (Johnston et al. 1995). In fact, respiratory viral infections are detected in the majority of asthma exacerbations; of these, about 60 per cent are rhinoviruses (Johnston 2007). Viral infections may also be involved in the development of asthma, but the evidence is less clear. Several long-term longitudinal studies have shown that respiratory syncytial virus (RSV) infections increase the risk of subsequent recurrent wheezing and asthma in early childhood (Sigurs et al. 2005). However, this risk may progressively decrease with increasing age (Stein et al. 1999). Other viruses have also been associated with asthma development including human rhinovirus (HRV) which may in fact be a more important risk factor than RSV (Lemanske et al. 2005). The mechanisms of viral-induced asthma are poorly understood, but it is possible that impaired innate immune responses may play a crucial role (Johnston 2007).

Paracetamol

It has been reported that prenatal paracetamol (or acetaminophen) use during pregnancy was a risk factor for asthma and wheezing in the offspring at 6–7 years of age (Shaheen et al. 2002, 2005). Similarly, several cross-sectional and longitudinal studies have reported that paracetamol use was associated in a dose-dependent manner with an increase in asthma in children and new-onset asthma in adults (Shaheen et al. 2000; Barr et al. 2004). Furthermore, national per capita consumption of acetaminophen was ecologically associated with the prevalence of wheeze, diagnosed asthma, and BHR in Western Europe (Newson et al.

2000). Some of these associations may have been due to confounding (e.g. confounding by indication), but this is unlikely to fully explain the positive associations in birth cohort studies (Shaheen et al. 2002, 2005), and longitudinal studies in adults that focused on new-onset asthma (Barr et al. 2004). The underlying mechanisms are unclear, but it has been suggested that paracetamol decreases glutathione levels in the lung, which may predispose to oxidative injury, bronchospasm, and an increased Th₂ response (Shaheen et al. 2002).

Allergens

Indoor allergens, particularly house dust mite allergens, are perhaps the group of possible asthma risk factors that have received the greatest attention. It is well established that in sensitized asthmatics, allergen exposure can trigger asthma attacks, and that prolonged exposure can lead to the prolongation and exacerbation of symptoms. However, most studies in children show only weak associations between allergen exposure and current asthma, even when the analyses are restricted to atopic patients and allergen avoidance has been accounted for (Pearce et al. 2000c). Also, secondary intervention trials have had mixed results (Gotzsche et al. 1998).

Furthermore, the evidence linking allergen exposure with new-onset asthma is weak (Pearce et al. 2000c). The key study linking allergen exposure in infancy to the subsequent development of asthma is that of Sporik et al. (1990) who followed 67 children with a family history of atopy. However, more recent longitudinal birth cohort studies found little or no association between early dust mite allergen exposure and asthma later in childhood (Burr et al. 1993; Corver et al. 2006; Tepas et al. 2006). For example, Burr et al. (1993) conducted a longitudinal study among 453 infants in South Wales with a family history of allergic diseases. Doctor diagnosed asthma and wheezing at age 7 was neither associated with mite allergen exposure as determined in the first 12 months nor at 7 years of age (ORs were not given). Similarly, in the German Multicentre Allergy Study, levels of mite and cat allergens in early life remained strongly related to specific sensitization at age 3–7 years (Lau et al. 2000, 2002), but no dose–response relationship between allergen exposure and any measure of asthma/wheeze at 7 years of age was found (Lau et al. 2000, 2002). Dust mite allergens are therefore unlikely to play a major role in the initial development of asthma. The evidence for a causal role of other allergens including cat, dog, cockroach and *Alternaria* allergens is even weaker (Pearce et al. 2000c).

Can the traditional risk factors explain the international patterns and time trends?

There is little evidence that the traditional risk factors can account for the global prevalence increases, or the international prevalence patterns observed. Furthermore, genetic factors alone are unlikely to account for a substantial proportion of asthma cases (Douwes and Pearce 2002) as the asthma prevalence increases have occurred too rapidly, although genetic susceptibility to changing environmental exposures may play an important role.

The global patterns of asthma prevalence are also inconsistent with the hypothesis that air pollution is a major risk factor for the development of asthma (Asher et al. 1998, 2006; Beasley et al. 1998). Regions such as China and Eastern Europe where there are some of the highest air pollution levels generally have lower asthma prevalence than the countries of Western Europe, North America, and Oceania, which have lower levels of pollution. It also appears unlikely that the international prevalence patterns can be explained by differences in smoking (Mitchell et al. 2002), or occupational exposures.

Allergen exposure is the risk factor that has perhaps received the most attention. In particular, it has been suggested that increases in indoor allergen exposures, through changes in lifestyle associated with Westernization, could account for the global increases in asthma prevalence (Sporik et al. 1990). However, the only study of English homes at two time points (1979 and 1989) did not demonstrate any change in house dust mite allergen levels (Butland et al. 1997), although marked increases have been observed in Australian studies (Peat et al. 1996).

The ISAAC (Asher et al. 1998) and ECRHS studies (Burney et al. 1996) have consistently found uniformly high levels of asthma prevalence in English-speaking countries, despite wide variation in house dust mite levels across these countries (Martinez 1997). In geographical areas in which dust mite exposure is very low or absent, including desert regions and mountainous regions the prevalence of asthma is as high as or even higher than that in other areas where house dust mite exposure is high (Martinez 1997).

Other available evidence on the association between allergen exposure and the subsequent risk of asthma at the population level is also less than persuasive. For example, Fig. 8.3.5 shows data from seven Australian surveys in centres with widely differing levels of mite allergen exposure; the overall prevalences of sensitization and asthma were both unrelated to the levels of house dust mite allergen (Der p 1) exposure in the six centres. The dominant

Fig. 8.3.5 Mean Der p 1 levels and prevalence (%) of house dust mite atopy, total atopy, and asthma in six areas of Australia.

Source: data from Peat JK et al. House dust mite allergens: A major risk factor for childhood asthma in Australia, *American Journal of Respiratory and Critical Care Medicine*, Volume 153, Issue 1, pp. 141–6, Copyright © 1996 American Thoracic Society. All Rights Reserved.

allergen varied between regions, but there was little overall difference in the prevalence of sensitization or of asthma despite the major differences in mite allergen levels.

The other asthma risk factors (e.g. diet, obesity, and/or paracetamol) may significantly contribute to the observed time trends and international patterns of asthma prevalence, but current evidence for this is scant.

Towards a new paradigm

Thus, although many of the traditional risk factors may exacerbate pre-existing asthma, the evidence that they may be involved in the initial development of asthma is limited. Also, there is little evidence that these factors account for the global prevalence increases.

Recent research has therefore shifted attention to factors that may 'programme' the initial susceptibility to asthma. This also involves a shift of attention from risk factors for asthma to protective factors, and the possible role of the loss of protective factors in the global increases in asthma prevalence (Pearce et al. 2000b). In particular, the increase in allergy and asthma contrasts strongly with a reduced prevalence of infectious diseases and corresponding decreased exposure to non-infectious microorganisms. This has been hypothesized as a possible explanation for the allergy and asthma epidemic (Eder et al. 2006), and is commonly referred to as the 'hygiene hypothesis'. The hygiene hypothesis has been prompted by evidence that overcrowding and unhygienic conditions were associated with a lower prevalence of atopy, eczema, hay fever, and asthma (Strachan 1989). Having a large number of siblings (especially older siblings) and attendance at daycare centres were determined to be particularly protective (Ball et al. 2000).

Several studies have shown associations between viral, bacterial or parasitic infections (e.g. hepatitis A, measles, *Schistosoma mansoni*) or Bacille Calmette–Guérin (BCG) immunization and a lower prevalence of atopy and allergies (Shaheen et al. 1996; Matricardi et al. 1997; Flohr et al. 2006), although findings have been inconsistent (Alm et al. 1998; Matricardi et al. 2000). It is possible that protection is specific to certain infections, at particular times of life. For example, one study found that croup (OR = 0.3; 95 per cent CI 0.12–0.72) and repeated ear infections (OR = 0.58; 95 per cent CI 0.35–0.98) in the first 12 months of life were inversely associated with atopy, whilst bronchiolitis was positively associated with asthma (OR = 2.77; 95 per cent CI 1.23–6.22) (Ramsey et al. 2007). Furthermore, it remains unclear as to what is the most important factor in protection from allergies and asthma; dose, route (oral–faecal versus airborne), type of infection (viral versus bacterial versus parasitic) or location (upper versus lower airways or digestive tract).

Environmental exposures to pro-inflammatory microbial agents (such as bacterial endotoxin) have also been suggested to be protective (Douwes et al. 2004). Studies have reported a significant inverse association between indoor endotoxin levels and atopic sensitization, hay fever, and atopic asthma (Braun-Fahrlander et al. 2002; Bottcher et al. 2003; Douwes et al. 2006). Recent work from ISAAC Phase II supports this, that is, combined across countries, household endotoxin levels were inversely related with asthma ever (OR = 0.53; 95 per cent CI 0.29–0.96) and current wheeze (0.77; 95 per cent CI 0.64–0.93) although the association with atopy was weaker (Gehring et al. 2008). However, the

available data regarding endotoxin are inconsistent with some studies showing an increased risk (Bolte et al. 2003; Perzanowski et al. 2006).

Exposures to different types of non-pathogenic bacteria may have differential effects on atopy and asthma. One birth cohort study showed that exposure to both Gram-positive and Gram-negative bacteria was inversely associated with asthma, whereas only Gram-negative bacteria were associated with allergic sensitization (Sordillo et al. 2010). More recently, studies in farming and non-farming environments have suggested that diversity of microbial species, rather than exposure to one particular microbial component, may be particularly protective (Heederik and von Mutius 2012). Consistent with these findings are recent observations that daycare centres—known to be associated with a lower prevalence of allergies and asthma in attending children—have been shown to be associated with considerable bacterial diversity (Lee et al. 2007) as have households with daycare attendees, or with cats and dogs (Maier et al. 2010).

In addition to specific agents with potential protective effects, subpopulations have been identified with low atopy and asthma rates compared to the general population. In particular, several studies have found consistently low prevalences of allergies and asthma in farmers' children, in both high- and low-income countries (Douwes et al. 2009; Genuneit 2012). These protective effects have also been observed in adult farmers (Douwes et al. 2007), despite increased risks of other respiratory conditions such as COPD (Schenker et al. 1998). The observed protective effects of farming on allergies and asthma have been particularly strong for animal contact (Douwes et al. 2008) or unpasteurized farm milk consumption (Loss et al. 2011), although the evidence for farm animals is mixed (Brunekreef et al. 2012). It remains unclear which specific factors are most important, but microbial exposures may play a role either through ingestion (lactobacilli, particularly through raw milk) or inhalation (endotoxin and other microbial components; see earlier). Whey proteins in raw milk may also be important (Loss et al. 2011). Protection conferred by farm residence may be dependent upon the type of farming conducted. For example, Ege et al. (2007) found that atopic asthma was inversely associated with animal exposures and raw milk consumption, but an effect for non-atopic asthma was only observed with silage exposure and agricultural farming. Recent data also suggest that farming may protect against asthma independent of atopy (Fuchs et al. 2012).

Furthermore, exposure to domestic animals may also confer protection. For example, pet ownership has been shown to be inversely associated with atopy and asthma in children and adults (de Meer et al. 2004b). This effect may be particularly strong with multiple pet exposures (Mandhane et al. 2009). In other parts of the world (Guinea-Bissau and Nepal) it has been shown that pigs and cattle in the home are associated with less atopy (Shaheen et al. 1996; Melsom et al. 2001). This is consistent with observations that animal contact in farmers' children may confer protection, and as hypothesized for the farmers' children, increased microbial exposures may play a role (Douwes et al. 2002b).

Although the specific immune mechanisms are not clear, it is believed that microbial exposures activate pattern recognition receptors (PRRs), such as Toll-like receptors (TLRs). This process is hypothesized to lead to downstream suppression of TH₂ cell expansion and therefore TH₂-mediated diseases, including

allergic asthma, hay fever, and eczema (Douwes et al. 2002a). Originally this was believed to function simply through altering the TH₁/TH₂ balance, that is, growing up in a more hygienic environment with less microbial exposure would enhance atopic (TH₂) immune responses, whereas microbial pressure would drive the response of the immune system—which is known to be skewed in an atopic TH₂ direction during foetal and perinatal life—into a TH₁ direction and away from its tendency to develop atopic immune responses (Martinez and Holt 1999). This model now appears to be oversimplistic, as demonstrated by parasitic infections which are associated with powerful TH₂ responses, but protect against atopy (described earlier). An alternative model has been proposed involving altered immunoregulatory mechanisms whereby microbial modulation (either directly or indirectly) of regulatory T cells may result in reduced expression of both TH₁ and TH₂ immunity. Some evidence for this was provided by a study in newborns (Schaub et al. 2009) and animal studies (Schabussova et al. 2012). However, at this stage the immunological mechanisms underlying the observed epidemiological associations remain largely unclear.

Can the 'hygiene hypothesis' explain the international patterns and time trends?

With the large proportion of asthma that is not attributable to atopy/allergy it is questionable whether the 'hygiene hypothesis' on its own can explain the large increases observed over the last decades or the global prevalence patterns, particularly since there is some evidence that non-atopic asthma may have increased more than atopic asthma (Thomsen et al. 2004). Also, although housing conditions are unlikely to have become more hygienic in inner city populations in the United States, asthma prevalence has increased significantly in those populations, particularly among African Americans living in poverty (Crater et al. 2001). Finally, the hygiene hypothesis is unlikely to explain why asthma prevalence is now apparently falling in some affluent countries (Chinn et al. 2004; Asher et al. 2006; Pearce et al. 2007), as exposures to factors that have previously been identified as being 'protective' (family size, endotoxin exposure, infectious diseases, pets, etc.) are likely to have decreased in more recent times rather than increased.

Thus, the hygiene hypothesis may not fully explain the current time and geographical trends in asthma prevalence. Nevertheless, whatever mechanism is involved, it is becoming increasingly clear that the 'package' of changes associated with Westernization may be contributing to the global increases in asthma susceptibility and prevalence.

Conclusions

What do these epidemiological findings tell us about the major causes of asthma and COPD?

The prevalence of COPD is still increasing particularly in women, and future projections indicate that the global burden of COPD will increase even further. The major causal risk factor is tobacco smoke, but a substantial proportion of COPD is also caused by occupational and indoor exposures, particularly in middle- and low-income countries. Only a minority of persistent smokers develop COPD, that is, those that are likely to be genetically susceptible for cigarette smoking. Similar to asthma, large international differences are observed in COPD prevalence even

when identical assessment methods are used, and these are not explained by age or cigarette smoking alone. Further understanding is required why some smokers develop COPD, and others don't, and what causes the striking differences in the global prevalence of COPD. However, we do know how to prevent COPD in the majority of cases, that is, smoking cessation is the most effective way to prevent the development of COPD and reduce disease progression.

In contrast, there remain major gaps in our current understanding of asthma aetiology. Although atopic sensitization is strongly associated with asthma, it appears to account for less than one-half of all cases, and there is little evidence that the traditional environmental asthma risk factors account for international prevalence increases. Recent decades have seen decreasing family size, increased hygiene, shift in dietary patterns, as well as increasing use of medical interventions such as immunization, antibiotics, and paracetamol. It seems that as a result of this 'package' of changes in the intrauterine and infant environment, we are seeing an increased susceptibility to the development of asthma and/or allergy. However, more recently the increase in asthma prevalence appears to have levelled off in many high-income countries, with some even showing a decrease. The reasons for this are unclear. Understanding why these changes are occurring, and ascertaining which elements of the 'package' of twentieth-century economic development and lifestyle changes are responsible, is essential in order to develop effective intervention programmes to halt the current global asthma epidemic.

Obesity

W. Philip T. James and Tim Marsh

Introduction to obesity

The prevalence of obesity and overweight has been increasing rapidly in all regions of the world. Those countries which saw large increases in the 1980s such as the United States and the United Kingdom are now starting to see a levelling in younger age groups and there is evidence that the increase is faster in countries undergoing rapid economic development and the nutrition transition. This is of great public health concern because projections suggest that as substantial increases in obesity occur, the morbidity associated with obesity and its complications will threaten gains in life expectancy and impose unsustainable economic burdens both on society and the health services. There is therefore an urgent need to intervene to reverse the growing epidemic.

Definitions of obesity

Obesity was originally defined by analysis relating to mortality, not morbidity, undertaken by the US Metropolitan Life Insurance Company before the Second World War. A body mass index (BMI) value (kg/m^2), adjusted for clothes and shoes (James 1976), of approximately 25 defined the limit above which death rates increased. The BMI value of 30 was 20 per cent above this upper 'normal' BMI limit of 25. However, later studies showed that the mortality risk of a smoker with a BMI of 22 was roughly equivalent to that of a non-smoker who had a BMI of 30 (Royal College of Physicians 1983). In 1995, the World Health Organization (WHO 1995) accepted BMI as the method for assessing degrees of underweight and overweight and took a BMI lower limit of 18.5 for distinguishing normal from underweight. This followed a series of earlier international analyses of adults' capacity to engage in heavy agricultural work. This BMI value therefore became the next cut-off point signifying undernutrition (James et al. 1988) (Table 8.4.1).

In 1997, following the WHO Expert Consultation on obesity, the implications of overweight and obesity were accepted as a global problem (WHO 2000). In the United States, higher BMIs were preferred but in Asia a lower BMI cut-off of 23 was accepted because above this value the risks of diabetes and hypertension in particular were unacceptably high. These susceptibilities to disease are increasingly linked to epigenetics, probably nutritionally induced in pregnancy and early childhood, rather than distinct ethnic differences in the genetics of disease susceptibility (Lillicrop and Burdge 2012). There have been recurrent analyses (Flegal et al. 2007, 2013) from the United States suggesting that being overweight is advantageous from a life expectancy point of view. These findings neglect to ensure that smokers and those who have never smoked are clearly

distinguished (Berrington de Gonzalez et al. 2010); observational studies are also very inappropriate as they do not take account of the well-known unintentional weight loss in those who are already ill, for example, with undiagnosed cancer who die within 1–5 years. Allowing for these factors, the data consistently suggest that non-smokers (and smokers when analysed separately) have, in a Western environment, the lowest mortality when BMIs are 22.5–25 (Lawlor et al. 2006; Keith et al. 2011). Identifying the mortality effects of overweight (BMIs of 25–29.9) require many years of follow-up with very substantial numbers of subjects (James 1976) and care to exclude other biases (Greenberg 2006). Other major studies with long follow-up periods show all-cause and ischaemic heart disease mortality rates were increased in the overweight group (Batty et al. 2006) and integrated analyses of 33 cohorts showed that the risk of non-fatal and fatal cardiovascular diseases increased progressively from a BMI of 20 whereas the impact on haemorrhagic stroke was not evident until BMIs were in the region of 30 (Asia Pacific Cohort Studies Collaboration 2004). Moreover, collaborative analyses of 57 prospective studies involving about 900,000 adults have found that in both sexes, mortality was lowest at about 22.5–25 kg/m^2 (Adams et al. 2006; Prospective Studies Collaboration 2009) and each 5 kg/m^2 BMI increase was associated with about a 30 per cent higher overall mortality. The first 3 years of follow-up had to be discarded because those who were already ill had lower BMIs and early deaths so without this adjustment the curves were J-shaped. Co-morbidities such as hypertension and diabetes in conjunction with higher body weights signify the degree of cellular and organ damage and are far more powerfully predictive of an early death than BMI alone (Padwal et al. 2011). This then can help in clarifying clinical decision-making.

Disability incurred by weight gain before death is a huge societal burden as disabilities affect younger individuals and may handicap them physically, mentally, psychologically, socially, and economically. Type 2 diabetes is now being diagnosed in overweight/obese children and adolescents (Park et al. 2012) and childhood overweight (unadjusted for adult BMI) is associated with adult cardiovascular outcomes and mortality (Reilly and Kelly 2011).

From a public health perspective the precise choice of cut-off point is arbitrary: the health hazards are progressive, age dependent, and not substantially changed at any particular cut-off point. The classic co-morbidities intrinsically linked to an excess BMI, for example, diabetes, hypertension, gall stones, and coronary heart disease are linearly related to BMI from a BMI nadir of about 19 or 20 so the choice of an upper normal value of 24.9 for individuals is very generous and ignores the issue of disability. WHO analyses use an estimated optimum population mean BMI

Table 8.4.1 The NIH and Asian adaptations of the WHO criteria for classification of overweight and obesity with their associated risks (Mancini et al. 2011)

Classification	BMI kg/m ²	Waist circumference and associated disease risk	
Europids (NIH)		Males/females ≤ 102 cm/≤ 88 cm	Males/females ≥ 102 cm/> 88 cm
Underweight	< 18.5	None	None
Normal	18.5–24.9	None	None
Overweight	25–29.9	Increased	High
Obese class 1	≥ 30	High	Very high
Obese class 2	30–34.9	Very high	Very high
Obese class 3	≥ 35	Extremely high	Extremely high
Asians		Males/females < 90 cm/< 80 cm	Males/females ≥ 90 cm/≥ 80 cm
Underweight	< 18.5	Low (but increased risk of other clinical problems)	Average
Normal	18.5–22.9	Average	Increased
Overweight	23–24.9	Increased	Moderate
Obese class 1	25–29.9	Moderate	Severe
Obese class 2	≥ 30	Severe	Very severe

of 21.0 where there was minimum risk of diseases associated with weight gain but at the same time a minimum risk of having a high proportion of adults with morbidity-related underweight, that is, BMIs lower than 17 (James et al. 1988). Non-smoking individuals are likely to have an optimum life expectancy and disability-free life if their BMIs remain at about 20 throughout life.

Other criteria for classifying excess weight gain: abdominal obesity

The INTERHEART international case-control study of coronary heart disease showed that the waist-hip ratio (WHR) was a far more sensitive measure of risk; fat deposition on the hips seems to be protective so that the risk associated with a high waist circumference (WC) is reduced by the extent to which fat is also laid down peripherally (Yusuf et al. 2005). However, WC measurement alone is also a better measure than BMI and does not require calculating a ratio; it is simple for both the public and professionals to understand and overcomes the need to measure the hip circumference, which in some societies is a culturally problematic measure to make except with female physicians taking considerable care.

The original choice of WC measurements was made so that they corresponded with the BMI cut-offs for overweight and obesity, that is, 25 and 30. These are the values which WHO then adopted (Table 8.4.1) for classifying—at least in Caucasians—excess abdominal fat. Values for the Asian population were later derived based on statistical calculations of the sensitivity and specificity of detecting hypertension or obesity at different WC levels. More recently the International

Table 8.4.2 Different waist circumference cut-off points selected by the International Diabetes Federation as part of their assessment of the metabolic syndrome

Country/ethnic group	Waist circumference (cm)	
Europids ^a In the United States, the ATP III higher values (102 cm male; 88 cm female), based on original small Dutch study of regression equivalents of BMIs 25 and 30 adopted by WHO, are likely to continue to be used for clinical purposes.	Male/female	≥ 94/ ≥ 80
South Asians Based on a Chinese, Malay, and Asian-Indian population	Male/female	≥ 90/ ≥ 80
Chinese	Male/female	≥ 90/ ≥ 80
Japanese ^b	Male/female	≥ 85/ ≥ 90
Ethnic South and Central Americans	Use South Asian recommendations until more specific data are available.	
Sub-Saharan Africans	Use European data until more specific data are available.	
Eastern Mediterranean and Middle East (Arab) populations	Use European data until more specific data are available.	

ATP, adult treatment panel.

^a In future epidemiological studies of populations of Europid origin, prevalence should be given using both European and North American cut-points to allow better comparisons.

^b Originally different values were proposed for Japanese people but new data support the use of the values shown above.

Reproduced with permission from International Diabetes Federation (IDF), The IDF consensus *worldwide definition of the metabolic syndrome*, Copyright © International Diabetes Federation, 2006, available from http://www.idf.org/webdata/docs/IDF_Meta_def_final.pdf.

Diabetes Federation proposed new criteria for specifying the metabolic syndrome—that is, a collection of risk factors including dyslipidaemia, hypertension, diabetes, and abdominal obesity—and adopted different values for different ethnic groups despite being derived very differently (Table 8.4.2) (James 2005). Waist measurements need to be standardized with the use of a non-stretchable tape measure in the horizontal plane half way between the lower rib cage and the iliac crest in the mid-axillary line. Without these criteria the errors in measurement can be serious.

There is a strong genetic influence on fat distribution but smoking and alcohol consumption also amplify the propensity to abdominal obesity. Early nutritional and other handicaps, revealed in part by low birth weights, are also associated with later abdominal obesity when even modest weight is gained in adult life. Thus, Indian, Chinese, and Hispanic populations with a marked history of early childhood malnutrition are particularly prone to abdominal obesity with a high WC even with BMIs lower than 25.

Children's criteria for overweight and obesity

WHO developed statistical criteria for specifying both underweight and overweight in children (WHO 1995). A child who is

underweight for their age, underheight for age, or underweight for height is classified as abnormal if not above the -2 standard deviations (SD) for their age and sex. Thus the greater than 2 SD for weight for height was taken as indicative of overweight with reference data from composite, meticulous US survey data but based on predominantly bottle-fed babies deemed to be healthy. The International Obesity Task Force (IOTF) group developed an international classification system for overweight and obesity in children (Cole et al. 2000) based on the BMI index (Dietz and Bellizzi 1999), and linking the childhood and adult definitions by taking, at age 18 years, those percentiles which corresponded to BMIs of 25 and 30 and using these same percentiles throughout the childhood age range for specifying overweight and obesity in childhood in girls and boys separately. Table 8.4.3 sets out the revised cut-off points to be used for this classification based on representative data from the Americas, Europe, and Asia (Cole and Lobstein 2012). It was recognized that BMI was a crude index of body fatness in children as well as adults especially in different societies with their different ages for the onset of puberty.

New definitions of 'normal' weight gain in children

The WHO has now developed a new approach for defining the normal growth of children (WHO 2007) with data from a major multinational study involving children in California, Norway, India, Oman, Ghana, and Brazil. Normal babies delivered at full term by non-smoking healthy mothers who agreed to breastfeed their babies exclusively for at least 4 months were monitored carefully with specific advice being given relating to immunization and other rearing practices. Further cohorts of pre-school children from similar environments were also chosen so that over a period of 6.5 years data on children's growth patterns were obtained. Surprisingly, whatever the ethnic background, the children's growth was almost identical and the variability in growth was far less than in the databases normally used for producing growth charts. This implies that if one takes these latest WHO ± 2 SD values as the standard for children up to 5 years, then a nation's new estimates of underweight and overweight prevalences will be greater. This particularly applies to the prevalence of overweight children because in both children and adults there is an increasingly skewed distribution of weights as the average weight for age rises (Fig. 8.4.1).

The WHO then developed a reference set of growth data for children from 5 to 20 years of age still based on US data and these are accepted by governments (de Onis et al. 2012b) even if paediatricians find them unrealistic and confusing in practice (Cole and Lobstein 2012). Overweight children by the new WHO classification show a greater propensity for hypertension, higher insulin and uric acid levels, and other indices of insulin resistance (de Onis et al. 2012a).

Tracking of body fat and BMI into adult life

Children are not born obese, but are certainly becoming more obese. Most studies providing more than one measurement during childhood and adolescence show that a persistence of weight status increases with age (Singh et al. 2008). The persistence was

also greater with increasing levels of overweight and perhaps more likely in girls than boys. Rolland-Cachera et al. (1987) originally focused on the issue of 'fat-rebound' in pre-pubertal school children but systematic reviews, for example, by Power et al. (1997) and Parsons et al. (1999) have found little evidence for the selective monitoring in the pre-pubertal phase for predicting the later emergence of obesity. Once children were over 5 years of age, being overweight incurred at least a 40 per cent risk of this overweight/obesity persisting into adult life and by the mid-teenage years the risk had increased to 60–75 per cent (Table 8.4.4). Barlow and Dietz (1998) advocated focusing on children over 3 years of age but there is now a very worrying increase in the prevalence of both high birth weight babies and obesity in 1–5-year-olds. The majority of 1–5-year-old children with BMIs greater than 2 SD of the new WHO limits are in lower-income countries with marked increases in these prevalences having occurred since 1990 (de Onis et al. 2010).

The predictive health significance of higher BMIs in childhood

Weight gain in children induces many early childhood problems including, in more severe degrees of overweight, developmental abnormalities of the weight-bearing joints and limbs. Metabolic problems such as insulin resistance, higher blood pressure, and dyslipidaemia are also evident in overweight and obese children even when young and higher BMIs even within the normal, that is, less than 2 SD range in 7–13-years-olds predict an early death and cardiovascular complications (Gunnell et al. 1998; Baker et al. 2007). This may simply reflect the probability of obese children remaining obese into adult life as it is difficult to disentangle an effect on mortality independent of the adult BMI achieved (Park et al. 2012). Those obese adults currently at high risk of diseases were born at a time when childhood obesity was relatively scarce so current rates of childhood obesity may prove to be more hazardous.

Genetics and obesity

Genes influence human physiology, its development, and adaptation but the rapid growth in obesity must be a consequence of environmental rather than genetic factors because the gene pool is relatively constant. Genetic factors are important in influencing the propensity to weight gain through gene–environment interactions. A genome-wide search for type 2 diabetes-susceptibility genes identified a common variant in the *FTO* (fat mass and obesity associated) and *MC4R* genes that predispose to diabetes through an effect on BMI. The 16 per cent of adults homozygous for the *FTO* risk allele weigh about 3 kg more and have a 1.67-fold increased odds of obesity. This is evident from the age of 7 years and reflects a specific increase in fat mass, perhaps expressed through increased appetite.

Neel originally proposed the 'thrifty gene' hypothesis (Neel 1962), that is, that the recurrent threat of famine and natural selection favoured genes for the highly efficient effects of insulin and the frugal use of glucose during times of little food with efficient storage of extra calories as fat during times of plenty. This hypothesis persists but if famines affected the evolution of all societies then identifying the gene clusters linked to the widespread propensity to obesity is not easy.

Table 8.4.3 Revised IOTF BMI cut-offs by age for childhood overweight and obesity

Age (years)	Boys			Girls		
	BMI 25	BMI 30	BMI 35	BMI 25	BMI 30	BMI 35

Childhood prevalence of obesity

Based on IOTF criteria, about 10 per cent of boys and 9 per cent of girls aged 5–17 years globally are overweight or obese, that is, a total of 118 million. The latest available regional prevalences using the IOTF definitions are given in Table 8.4.5.

In young children, there is emerging evidence of a flattening of the upward trends. Thus in the UK, obesity in children between the ages of 2 and 10 years increased from 10.1 per cent in 1995 to 14.6 per cent in 2010 but then was stable between 2008/2009 and 2010/2011 for 4–5-year-olds. Similarly, UK 2–15-year-olds' weights

Fig. 8.4.1 The skewed distribution of BMI with increases in the average population BMI.

Source: cross-sectional data from Rose G., Population distributions of risk and disease, *Nutrition, Metabolism and Cardiovascular Diseases*, Volume 1, pp. 37–40, Copyright © 1991, illustrates the progressive marked increase in obesity rates for modest increases in mean BMI. Those in the upper BMI range for each population distribution represent the genetically susceptible individuals to weight gain. The usual Caucasian cut-offs for overweight and obesity are shown together with the Asian upper limit of 'normal' BMI.

The proportion of obese adults who had been originally overweight as a child was usually 3–10-fold lower than the corresponding probability of overweight children maintaining their excess weight into adulthood.

consistently increased up to 2004 but then gently declined (National Obesity Observatory 2013).

In the United States, there is also a decreasing prevalence or stabilizing of trends (Yanovski and Yanovski 2011). Obesity in 2–5-year-old children decreased from 16.7 per cent in 2003 to 14.7 per cent by 2005 and then stabilized but with an upward trend in overweight (Olds et al. 2011). Analysis across nine countries including England, United States, Sweden, China, Australia, Netherlands, and Switzerland also reported a flattening of childhood obesity for 2–19-year-old children and teenagers (Rokholm et al. 2010). These promising trends may not persist and annual monitoring of health survey data is imperative for progress to be evaluated.

The prevalence of adult overweight and obesity

Although obesity, measured as BMI, is an index of excess body fat there are a number of ways of measuring excess body fat itself, such as bio-impedance, densitometry, and plethysmography, but the last two are very expensive and have not been used for population studies. Evidence from a range of countries shows that weight tends to increase progressively as individuals age, until it reaches a peak and then begins to fall—usually after the sixth decade of life. Most data on BMI are based on self-reported heights and weights which usually underestimate the prevalence and makes comparisons difficult with measured data.

Overweight and obesity have now become a global problem and the hazards of excess weight gain are beginning to match the burden of cardiovascular diseases where the developing countries now have about 80 per cent of the world's burden for the non-communicable diseases according to 2010 WHO estimates (WHO 2011). However, only 16 per cent of global

health expenditure occurs in the poorer non-Organisation for Economic Cooperation and Development (OECD) countries even though they represent 82 per cent of the world's population (WHO 2012b). Table 8.4.6 shows the regional prevalences of overweight and obesity in adults. The table provides an illustration of the age-related adult changes in the prevalences in different regions of the world and shows that the main increase occurs in 20–40-year-olds.

A recent WHO report (WHO 2013) recommended the global monitoring of both overweight and obesity prevalences in adolescents (defined according to the WHO growth criteria) and adult measured BMIs.

The nutrition transition

The economic development of a country and particularly the urbanization of populations is associated with major increases in obesity prevalence (Popkin 2006). In poorer communities, middle-aged women are the first to become overweight and then, as the economy develops, women become progressively heavier with men then beginning to catch up. In developing societies, the more affluent have higher prevalences of obesity with the average BMI of the population increasing progressively as national incomes rise to a gross domestic product of about \$5000 and then peaks in women at \$15,000 and in men at \$17,000 (Ezzati et al. 2005). Then, as societies' economies improve, there is a reversal of the socioeconomic gradient with the more affluent becoming slimmer and having lower obesity rates than the poor. With average increases in weight, the proportion of obese individuals increases markedly because of the skewing of BMI distributions (Rose 1991). Fig. 8.4.1 also highlights the fact that the most genetically sensitive members of the community are those found in the upper distributions for their society.

The hazards of excess weight in adults

Being obese significantly increases the risk of developing non-communicable diseases. Table 8.4.7 lists medical conditions associated with excess weight gain (IOTF 2010). Conditions found to be associated with high BMIs by the Institute for Health Metrics and Evaluation (IHME) 2010 global burden of disease research group are included (Lim et al.

2012). This extended set of medical conditions has not been independently validated and several of the cancer relationships were not found to be robust in the exhaustive and meticulously collated latest World Cancer Research Fund and American Institute of Cancer Research assessments (2007) of the role of weight gain in cancer development and prevention. There is evidence that obesity, particularly in mid and later life, is a major risk factor for cognitive decline (Proffenno et al. 2010), both directly and indirectly because the associated hypertension and type 2 diabetes increase the speed of vascular induced changes in the brain.

The physical and other impacts of weight gain must also be considered. The impact on respiratory function is important with overweight children and adults becoming unable to engage in strenuous physical activity. Obese adults walking slowly already use up to 60 per cent of their maximum exercise capacity. Thus obese adults often do less than normal because their physical exertions are very energy consuming. Weight gain is also a marked handicap in those with any degree of respiratory impairment. Asthmatic and chronic obstructive respiratory disease patients can markedly improve their exercise tolerance and comfort if they lose weight. Weight gain also increases the risk of sleep apnoea which is associated with a large neck and a tendency to obstruct breathing. Subjects stop breathing for a quarter or half a minute before then showing marked intakes of breath as their drive to breathe takes over for perhaps a minute or two before the cycle is repeated. This feature, usually evident at night and seemingly innocuous, is a major medical handicap associated with drug-resistant hypertension because of the persistent induction of the sympathetic nervous system by the repeated episodes of anoxia. When severe it is also associated with higher mortality rates and can cause traffic accidents as abdominally obese adults with thick necks fall asleep as they drive their vehicles.

Back and joint pains are another major problem leading to greater time off work for overweight and obese patients. The mechanical force on joints and the strain on the muscular skeletal system is marked leading to frequent work absenteeism and reactive depression among many overweight and obese subjects.

The medical and other costs of excess weight

Whilst obesity is responsible for an increasingly significant burden of disease, these observations do not resonate strongly outside the health community. What does have impact with policymakers and politicians is being able to calculate the potential avoidable direct and indirect health costs of excess weight gain as in the UK Foresight *Tackling Obesities* report (Foresight 2007). The direct costs of obesity represent the monetary value of healthcare resources devoted to managing obesity-related conditions including the costs incurred by excess utilization of ambulatory care, hospitalization, medications, radiological or laboratory tests, and long-term care (including nursing home care). There is a general consensus that obesity places a significant financial

burden on the healthcare system (Withrow and Alter 2011). A large proportion of the variation in cost estimates relates to the multiplicity of methods used. Finkelstein et al. (2009) found that US obese patients incur 46 per cent higher inpatient costs, 27 per cent higher physician visits and outpatient costs, and 80 per cent higher spending on prescription medications compared to normal weight individuals. The annual medical costs of obesity in the US were estimated as \$75 billion in 2003; they also accounted for 4–7 per cent of total healthcare expenditure in the Netherlands (Seidell 1995) and 2 per cent in Australia (Segal et al. 1994). The European Union's combined direct and indirect costs of obesity in 2002 were approximately €33 billion a year and in 2007, the UK projected that the ongoing rise in obesity will add £5.5 billion in medical costs to the National Health Services by 2050 (Foresight 2007).
